Abstract [under 100 words….]

Identification of noncoding cancer "drivers" from thousands of somatic alterations is a difficult and unsolved problem. Here, we developed SMAP, a flexible framework to annotate and prioritize cancer regulatory mutations. The framework combines an adjustable data context summarizing large-scale genomics and cancer-relevant datasets with an efficient variant prioritization pipeline. To prioritize high impact variants, we developed a weighted scoring scheme to score each mutation's impact through analyzing conservation, loss-of and gain-of function events, gene associations, network topology and multiple-sample recurrence. Cancer specific information is then used to further highlight potential oncogenic relevant candidates.

Keywords

Annotation, Prioritization, Regulatory driver, Cancer somatic alterations

Background

Cancer genome sequencing generally identifies thousands of somatic alterations in individual tumor genomes. A few of them, called drivers, contribute to oncogenesis, whereas the majority are passenger mutations accumulated during cancer progression [1]. Systematic studies of human cancer genomes have discovered a wide range of driver genes [2-6]. However, comparatively less effort has been invested in the noncoding portions of the genome. Recent discovery of somatic mutations in telomerase reverse transcriptase (*TERT*) promoter shows that regulatory variants may constitute driver events [7-10]. With the decrease of sequencing cost, international cancer consortia, such as TCGA (The Cancer Genome Altas) and ICGC (The International Cancer Genome Consortium), plan to perform large-scale cancer whole-genome sequencing in the near future. Thus, there is a great demand for high-throughput computational methods analyzing those variants.

In contrast to coding variants, the functional impact of noncoding variants is more difficult to evaluate, due to the lack of knowledge about noncoding regions. The important role of regulatory variants in various diseases has generated a great deal of interest in studying noncoding sequences [11-14]. Projects aiming to uncover potential regulatory sequences, such as The Encyclopedia of DNA Elements (ENCODE) [15] and 29 Mammals Project [16], provide an unprecedented opportunity to interpret noncoding variants. Studies have shown that disease-associated single nucleotide polymorphisms (SNPs) identified by Genome-wide Association Studies (GWAS) are significantly enriched in ENCODE regions [17]. A number of tools have been developed using these data to annotate potential regulatory variants or to suggest most likely causal variants in linkage disequilibrium with GWAS SNPs, such as Haploreg [18], RegulomeDB [19], ANNOVAR [20], GEMINI [21], FunciSNP [22] and VEP [23]. Recently, two computational approaches – GWAVA and CADD were published to predict the deleterious effect of variants genome-wide [24, 25]. These two methods utilized

machine-learning models trained on potential pathogenic variants or nearly fixed/fixed human derived alleles to distinguish deleterious variants from neutral ones.

While much work has been done for germline variants, this is not the case for cancer somatic mutations. Through analyzing the variation patterns of natural polymorphisms, we have published a prototype approach (FunSeq) to identify potential noncoding drivers [26]. Here, we report a more elaborate and flexible framework - SMAP, built up from the previous work, to annotate and prioritize somatic alterations integrating various resources from genomic and cancer studies. The framework consists of two modules – (1) optional rebuilding of the data context by uniformly processing large-scale datasets and (2) high-throughput variant prioritization pipeline. Users could either use the pre-existing or customized data context to prioritize variants. Key features of our method include - 1) we integrated functional annotations to identify potential regulatory variants and predicted nucleotide-level loss-of and gain-of function events; 2) we examined whether variants occurred in noncoding regions that are less likely to tolerant mutations through analyzing both evolutionary and human population-level conservation; 3) we systematically associated variants to target genes using data from Roadmap Epigenomics Project and 4) we further investigated these variant-gene linkages, incorporating network topology analysis, gene function prioritization, differential gene expression detection and sample-specific epigenetic or open chromatin profiles. To prioritize 'high-impact' variants, we developed a weighted scoring scheme that takes into account the relative importance of various features, based on the mutation patterns observed in natural polymorphisms. Using 570 whole-genome sequenced cancer samples together with COSMIC data, we have also created a recurrence database, to which user-input genome will be compared.

Besides mutations in the *TERT* promoter, no other regulatory variants have been functional characterized as cancer drivers. Thus, due to a lack of gold standard for regulatory cancer drivers, we used somatic recurrent mutations and known germline pathogenic variants to evaluate the performance of our method. Our method has good prediction power for both somatic recurrent and germline pathogenic regulatory variants, and more importantly it contains multiple cancer-specific features, such as differential gene expression detection between tumor and matched normal samples. As a test case, we also applied our method to an individual tumor genome with the known *TERT* promoter mutation. Our method is able to prioritize the variant and provides a hypothesis of its potential functional impact. This shows that our method can help researchers and clinicians to prioritize a few somatic regulatory mutations for further studies.

Results and discussion

High-throughput technologies have generated huge amount of genomics data in the past decades. How to mine and integrate these data to tackle particular scientific question remains a challenge. In this study, we first build an organized data context by processing large-scale genomics and cancer resources into small-scale informative data and then use them to annotate and prioritize cancer

Variants in potential regulatory elements

Regulatory elements, especially promoters and enhancers, are capable of regulating the expression of specific genes. We collected functional annotations from ENCODE [15] (transcription factor binding sites and the high-resolution motifs within them, enhancers from genome segmentations, ncRNAs and DNase I hypersensitive sites) and regions that are highly occupied by transcription factors (HOT) from *Yip et al.,* [27] to annotate variants in potential regulatory sequences.

YAO FU 7/25/14 12:15 PM
Deleted: Functional impact of variants in regulatory regions is generally restricted to *cis*-acting effects that control the spatial and temporal patterns of gene expression [13]. Activation of regulatory elements is associated with the underlying epigenetic or open chromatin landscape, which is largely cell-line specific [28]. Therefore, we provide a module to incorporate sample-specific epigenetic or open chromatin profiles to denote corresponding activation or inactivation of regulatory sequences; for example, enrichment of H3K27ac may indicate active state of enhancers in the sample.

Nucleotide-level impact of regulatory variants

Regulatory mutations can cause transcriptional alterations by either loss-of or gain-of- function effects. Loss-of-function events in transcription factor binding motifs are likely to cause deleterious impact [26, 29, 30]. Variants decreasing the position weight matrix (PWM) scores could potentially alter the binding strength of transcription factors, or even eliminate the binding. Our framework consists of a module to detect motif-breaking events – defined as variants decreasing PWMs (Material and Methods). Meanwhile, gain of new binding sites caused by somatic mutations can constitute driver events [7-10]. To the best of our knowledge, there is no automated tool to detect such events in whole tumor genomes. We incorporated a gain-of-motif scheme to scan and statistically evaluate [31] all possible motifs created by mutated alleles in promoter or enhancer regions. For each variant (SNV or indel), we concatenated it with +/- 29bp nucleotides around it and calculated sequence score for each possible motif against the PWMs. Gain-of-motif events are identified when sequence score with mutated allele is significantly higher than the background ($p < 4e-8$), whereas that with germline allele is not. Our scheme is validated by the detection of motif-gaining events caused by the two driver mutations in *TERT* promoter; see later (Additional file 1: Table S1).

Deleted: Sequence conservation of variants

Variants in conserved regions

Sequences that are under strong negative or purifying selection are thought to have important biological functions [32]. In previous studies, oncogenes or tumor suppressor genes are found to experience higher intensity of selective pressure than other disease-related and non-disease genes [33]. Cross-species genome comparison is a powerful approach to identify evolutionary conserved sequences. For example, GERP [32] is developed to estimate the position-specific evolutionary constraint; sequences that are shared across species are defined as ultra-conserved elements [32]. Meanwhile, human population-level constrained regions are identified from 1000 Genomes [32] using depletion of common polymorphisms. We combined these data to detect potential deleterious variants in noncoding sequences. Each variant will be annotated with the corresponding conservation information.

Associating regulatory elements with likely target genes

Functional genomic studies have characterized biological functions of large number of genes. Associating regulatory variants to coding genes, especially

those well-known cancer driver genes, will help us understand the regulatory mechanisms that govern the oncogenesis and potentially benefit therapeutic treatment. Positioned distant to their target genes, regulatory elements regulate gene expression through long-range interactions [34]. The linkages between regulatory elements and genes remain elusive. To explore likely functional consequences of regulatory noncoding variants, we comprehensively define regulatory element-target gene pairs through correlating various epigenetic modifications with gene expression levels. We considered the enhancer marks H3K4me1 and H3K27ac as two types of activity signals, and DNA methylation as an inactivity signal. Using ChIP-Seq and RNA-Seq data from the Roadmap Epigenomics Mapping Consortium (REMC), for each regulatory element-candidate target gene pair, we computed the correlations of H3K4me1 and H3K27ac and the anti-correlations of DNA methylation at the regulatory element with gene expression levels across ~20 tissue types (Material and Methods). In total, we identified ~XXXX significant associations involving ~769K distal regulatory elements and ~17K genes (Material and Methods; Figure S1). All noncoding variants in these regulatory elements could be associated with potential target genes (with various association confidence). To incorporate the ever-increasing amounts of genomic data, we include a pipeline for users to extend the data context with their own data, for example, users can input annotation regions or chromatin marks to find novel associations between regulatory elements and coding genes (Additional file 1).

Network analysis of variants associated with genes

Unlike germline mutations, somatic alterations are not expected to be under organism-level evolutionary selection pressure and thus are more likely to affect functional centers in gene interaction networks [35]. Network studies have found that cancer genes possess high topological centralities, even higher than essential genes [26, 35]. We used the regulatory element-target gene pairs to connect noncoding variants into a variety of networks: protein-protein interaction, regulatory and phosphorylation networks [26, 34, 36]. For each noncoding variant, we calculated the scaled network centrality (the percentile after ordering centralities of all genes in a particular network) of the associated gene in each network (Material and Methods). Amongst the different network centralities, we used the maximum centrality as the network disruptive measure of the variant. The higher this value, the more likely the variant would be deleterious. We make the scheme flexible so it can integrate user networks in addition to the pre-collected networks.

Recurrence database from cancer whole-cancer whole-genome sequencing

Recurrent elements across cancer samples

One criterion to identify cancer driver genes is to examine their mutational recurrence across multiple samples [3]. We extended the concept to noncoding regulatory elements, such as transcription factor binding sites. Our method is able to detect recurrent same-site mutations, genes and regulatory elements from user-input cancer samples.

When having small sample sizes, comparisons with available tumor genomes would be useful to discover recurrent mutations. Related to this, we have created a recurrence database (Recurrence DB) (including regulatory elements, coding

YAO FU 7/25/14 11:19 AM
Deleted: Recurrence database from cancer whole-genome sequencing

genes and the same-site mutations) with publicly available cancer whole-genome sequencing data. Currently, we have identified recurrent loci or sites from 570 samples of 10 tumor types [37-39] and from COSMIC [40] (Table 1; Material and Methods). Variants in user-input tumor genomes are compared to the recurrence database and the results in different cancer types are reported in the output. The use of the database along with our framework would provide higher confidence in prioritization of noncoding drivers (Figure 2). The database will be updated with newly available dataset.

Weighted scoring scheme to prioritize variants

All of the above features are used to annotate and score variants (Figure 2). To integrate the various features to predict 'high-impact' somatic alterations, we developed a weighted scoring scheme, taking into account the relative importance of each feature. Features used to score variants are shown in Figure 3. In general, features can be classified into two classes - discrete and continuous. Discrete features are binary, such as in ultra-conserved elements or not. For continuous features, taking 'motif-breaking score' as an example, the values would be the changes in PWMs. We weighted each feature based on the mutation patterns observed in natural polymorphisms (Material and Methods; Additional file 1: Table S3). Constrained by selective pressure, natural variations tend to arise in functionally unimportant regions. Thus, features that are frequently observed are less likely to contribute to the deleteriousness of variants and are weighted less. We calculated the information content to denote the importance of each feature. For each cancer mutation, we scored it by summing up the information contents of all its features (details in Material and methods). Variants ranked on top of the output are those with higher scores and are most likely to be deleterious.

Highlighting variants using prior knowledge of genes and user annotations

Interpretation of the functional impact of noncoding variant can be greatly enhanced if the function of its target protein-coding gene is known. Many cancer genes are known to play a crucial role in cell proliferation and DNA repair. We incorporated prior knowledge of genes, such as known cancer-driver genes [32], genes involved in DNA repair [32] and actionable genes ('druggable' genes) [41] to annotate noncoding variants that are likely to be involved in cancer development and growth or their associated genes could be used as drug targets. In addition, user-specific gene lists can be easily input (Additional file 1).

Variants in regulatory elements may disrupt the expression of coding genes. Differential expression of target genes in cancer samples indicates the potential effect of noncoding variants. We provide a "differential gene expression analysis" module (Figure 1) to detect differentially expressed genes in cancer samples (relative to matched normal) from RNA-Seq data. Lists of differentially expressed genes can be generated and used to annotate variants.

We also provided a module for users to incorporate their own annotations. Impact of variants in regulatory regions is generally restricted to *cis*-acting

effects that control the spatial and temporal patterns of gene expression [13]. Activation of regulatory elements is associated with the underlying epigenetic or open chromatin landscape, which is largely cell-line specific [28]. For example, enrichment of H3K27ac may indicate active state of enhancers in a particular sample. Therefore, it would be useful to incorporate sample-specific epigenetic or open chromatin profiles to annotate variants in activated or inactivated regulatory sequences.

All features used in our method and corresponding details are described in Additional file 1: Table S2.

Performance on regulatory cancer somatic variants and germline pathogenic variants

Applied to somatic recurrent variants

Currently only two known regulatory variants are thought to act as cancer drivers. Hence, to evaluate the performance of our scoring scheme, we used recurrence to approximate the deleteriousness of somatic variants. Recurrence is considered as one potential sign of positive selection amongst tumors and is more likely to be associated with driver events [3]. We examined recurrence from two perspectives – recurrence at the exact same site and recurrence in the same regulatory element. First we classified COSMIC regulatory somatic variants [40] as same-site recurrent or non-recurrent (Material and Methods) [25]. Our method scores recurrent variants higher than non-recurrent ones (Wilcoxon rank-sum test: p-value < 2.2 e-16; Figure 4A). Variants that occur in more than 2 samples have higher scores than those that are in 2 samples. Next we evaluated variants in recurrent regulatory elements using a separate dataset. We ran our pipeline on 119 breast cancer samples [37] and classified variants as occurring in recurrent elements or not (Material and Methods). We find that variants in recurrent elements get significantly higher scores (Wilcoxon rank-sum test: p-value < 2.2e-16; Figure 4B) than variants elsewhere. Similar patterns are observed with other cancer types (Additional file 1: Figure S6). Results from CADD and GWAVA are shown in Additional file 1: Figure S5.

We note that cancer is a very heterogeneous disease and distinct molecular subtypes may involve unique oncogenic mechanisms. Thus, tumor samples from different patients may involve different driver events. These unique drivers would not show recurrence across samples. Furthermore, in the absence of large sample sizes, it might be impossible to detect recurrence of mutations. Our method would be especially useful in such scenarios, since it has the ability to prioritize deleterious variants in each tumor genome. Moreover, the functional relevance and hence the biological mechanism by which drivers act is largely unknown. Our method provides an in-depth annotation of such variants, including the relative contribution of each feature to its deleteriousness. This knowledge would greatly help understand the potential oncogenic mechanisms.

Applied to germline pathogenic variants

Disease studies have identified many noncoding pathogenic variants. Designed primarily for somatic mutations, our framework contains several features that

YAO FU 7/26/14 3:20 PM

are applicable to germline variants. Thus, we tested the ability of our method to distinguish germline pathogenic variants from neutral ones. We also did possible comparisons with other germline variants prioritization tool [24, 25]. We obtained pathogenic regulatory variants from HGMD [42] and three sets of controls from *Ritchie et al* [25] – 'unmatched', 'matched TSS' and 'matched region' (Material and Methods). Our method scored HGMD variants higher than all controls, with AUC scores of 0.86 (for 'unmatched'), 0.74 (for 'matched TSS') and 0.62 (for 'matched region') (Figure 4C and 4D). Results from CADD [24] using the same dataset are shown in Additional file 1: Figure S7 (AUC scores: 0.75 ('unmatched'), 0.68 ('matched TSS') and 0.61 ('matched region')). As negative sets are much larger than positive set, one concern with AUC scores is that the prediction power may come from the ability to predict negatives instead of positives. Thus we examined precision and recall to capture the ability of our method to predict positives (Additional file 1: Figure S8). Generally speaking, our method has good prediction power for pathogenic regulatory variants. In addition, GWAS SNPs show higher scores than matched common polymorphisms (mean values: 0.41 vs. 0.34, p-value < 2.2e-16; Material and Methods; Additional file 1: Figure S9).

A case study: somatic variants from an individual cancer genome

High recurrence of the *TERT* promoter mutations implicates their important roles in tumorigenesis [7]. Among the 570 cancer samples we collected, 7 samples contain the *TERT* promoter mutation (chr5: 1295228). We used one Medulloblastoma sample as an example to prioritize regulatory variants from whole-genome sequencing. Amongst the 2,183 somatic single nucleotide variants, the *TERT* promoter mutation ranks the 2nd (0.09%). Our method further suggests potential functional impact of this variant. As shown in Table 2, this mutation occurs in ENCODE regulatory regions, creates a novel ETS binding motif and potentially affects a highly connected and known cancer gene –*TERT*. It is also found in another 5 liver samples and 54 COSMIC samples in our recurrence database. Besides DNA sequences, epigenomics or transcriptome could also be altered in cancer genomes. These data provide sample-specific activation or inactivation signatures of regulatory sequences. If provided, our framework is flexible in integrating those data into our annotation scheme (refer to Additional file 1 for details).

We also applied CADD and GWAVA on the Medulloblastoma sample. CADD ranked the *TERT* promoter mutation as 224th (10.3%) and GWAVA ranked it as 25th (1.15%) with the matched region model (Additional file 1: Figure S10). However, only our method shows that the mutation corresponds to gain-of an ETS binding motif in the promoter of a cancer driver gene. Results of additional 6 samples are shown in Additional file 1: Table S4.

Output format and performance

SMAP is a Linux/Unix based tool with a web-server available at http://smap.gersteinlab.org. The code is also posted under GitHub - http://github.gersteinlab.org/SMAP. It takes VCF or BED formatted cancer variants and generates results in either BED or VCF format (refer to Additional file 1 for examples). Users can retrieve or visualize results in concise tables

YAO FU 7/26/14 3:23 PM
Deleted: 'Unmatched' control consists of likely neutral polymorphisms randomly selected from 1000 Genomes Phase1. Restrictions of '2Kb around TSS' and '1Kb around HGMD variants' are applied to 'matched TSS' and 'matched region' controls, respectively.

through the web interface (Additional file 1: Figure S11 and S12). We also pre-computed easy-query scores for all possible regulatory SNVs of GRCh37/hg19 on our website (the 'core scores' in Figure 2).

SMAP runs in a tiered fashion. Building data context from bulk of data resources is time-consuming. Currently it takes about one week (on ~20 4-core 3.00-Ghz 16GB RAM PowerEdge 1955 nodes) to rebuild the data context based on pre-processed genomics data, such as ENCODE peak calls. The data context will be updated regularly to keep it up-to-date. Users can input additional data to customize the data context upon the existing one. Variant prioritization step is quite efficient. It takes ~2-3 mins to prioritize one genome with thousands of variants on a QEMU Virtual CPU version (cpu64-rhel6) @ 2.24-GHz 1 processor Linux PC with 20GB RAM, and a 500 GB local disk. Time comparison with CADD and GWAVA is in Additional file 1: Table S3 (SMAP is two times faster with equal number of variants). In addition, we implemented parallel-processing fork manager for efficient memory utilization to tackle multiple genomes in a single run. With a flexible and modularized structure, researchers can restructure the pipeline to incorporate more data and new features.

Conclusions

We have developed a method integrating various genomic and cancer resources to prioritize cancer somatic variants, especially regulatory noncoding mutations. User data can be easily integrated into the framework. We believe that the software would be useful for researchers to identify a few somatic events among thousands for further in-depth analysis to understand the mechanisms underlying oncogenesis.

Material and Methods

Data resources

We collected polymorphisms from 1000 Genomes Project Phase 1 [43], GERP scores and ultra-conserved elements from [44, 45], sensitive/ultra-sensitive regions from [26], functional genomics data from ENCODE [15], highly occupied regions (HOT) from [27] and histone modifications ChIP-Seq and gene expression RNA-Seq data from REMC [46]. Cancer driver genes are the union of genes from *Vogelstein et al.*, cancer gene consensus and COSMIC [2, 47]. DNA repair and actionable genes are from [41, 48]. Binary protein-protein interaction network is from InWeb [49] and HINT [50]. Regulatory and phosphorylation networks are obtained from *Gerstein et al.,* [34] and *Lin et al.,* [36] respectively. Whole-genome somatic alterations contain 506 cancer genomes from *Alexandrov et al.,* [37] and 64 prostate cancer samples from [38, 39].

High-impact variants in motifs: Nucleotide resolution effect

User-input variants are first filtered against natural polymorphisms based on user-defined minor allele frequency (MAF) threshold to get rid of unlikely somatic variants (hg19). Currently, SNVs and small indels (<=20bp) will be analyzed.

1. Motif breaking
When variants hit transcription factor binding motifs under ENCODE Chip-Seq peaks, we examined their motif breaking or conserving effect using position weight matrixes (PWM). Motif-breaking events are defined as variants decreasing the PWM scores, whereas motif-conserving events are those that do not change or increase the PWM scores [30] (we calculated the difference between mutated and germline alleles in the PWMs). Variants causing motif-breaking events are reported in the output together with the corresponding PWM changes. Transcription factor PWMs are obtained from ENCODE project [15], including TRANSFAC, JASPAR motifs.

2. Motif gaining
Whole-genome motif scanning generally discovers millions of motifs, of which, a large fraction are false positives. We focused on variants occurred in promoters (defined as -2.5kb from transcription starting sites) or regulatory elements significantly associated with genes. For each variant, +/- 29bp are concatenated from the human reference genome (motif length is generally <30bp). For each PWM, we scanned the 59bp sequence. For each candidate motif encompassing the variant, we evaluated the sequence scores using TFM-Pvalue [31] (with respect to the PWM). Given a particular PWM (frequencies are transformed to log likelihoods), sequence score is computed by summing up the relevant values at each position in the PWM. If the p-value with mutated allele <= 4e-8 and the p-value with germline allele > 4e-8, we define the variant creating a novel motif. The process is repeated for all PWMs and all variants. The sequence score changes are reported in the output.

Associating regulatory elements to likely target genes

We define both proximal and distal associations. For proximal associations, we assign variants in gene promoters, introns or UTRs to their nearby genes. For distal associations, in addition to those identified in [27], we further expanded the method to all ENCODE non-coding regulatory elements and identified ~2,225K significant associations between ~769K regulatory elements and ~17K genes (see below). The distributions of regulatory element-gene associations are shown in Figure S1. The median number of associations is 22 and 2 for per gene and per regulatory element, respectively. The association confidence is reported in the output for each regulatory element - target gene pair.

Correlating histone modifications with gene-expression data to identify likely target genes of distal regulatory elements

1. Definition of distal regulatory modules (DRMs)
We started with a list of regulatory regions from three different types, namely transcription factor binding peaks (TFP), DNase hypersensitive sites (DHS) and Segway/ChromHMM-predicted enhancers. All regulatory regions at least 1kb from the closest gene according to the Gencode v7 annotation [51] were defined as a distal regulatory module (DRM).

2. Identifying potential regulatory targets of each DRMs
We grouped different transcripts of a gene sharing the same transcription start

site as a transcription start site expression unit (tssEU). For each DRM, we first considered all tssEUs beyond 10kb but within 1Mb from it as its candidate targets. We then correlated some activity/inactivity signals at a DRM and the expression of its candidate target tssEUs, and called the ones with significant correlation values as potential DRM-target pairs as follows.

At the DRMs, we considered the enhancer marks H3K4me1 and H3K27ac as two types of activity signals, and DNA methylation as an inactivity signal. The activity level of each DRM was defined as the number of sequencing reads aligned to the DRM from the corresponding ChIP-seq experiments. The methylation level of a DRM was defined as follows. For each CpG site i within a DRM, we counted the number of reads that support the methylation of it (m_i), and the total number of reads covering it (n_i). The methylation level of the DRM was then defined as the ratio of their sums across all CpG sites in the DRM, $\frac{\sum_i m_i}{\sum_i n_i}$. For each tssEU, we defined its expression level as the number of RNA-seq reads aligned to the [TSS-50, TSS+50] window. Both the activity signal levels and gene expression levels were normalized by the total reads, then multiplied by one million to keep them within an easily readable range of values.

We collected all bisulfite sequencing, ChIP-Seq and RNA-Seq data from the Roadmap Epigenomics project website [46] (EDACC release 9[1]). We considered 19 tissue types with data for both the activity signals and gene expression, and 20 tissue types with data for both the inactivity signal and gene expression. For RNA-seq, we used the paired-end 100bp Poly-A enriched data sets. For experiments with replicates, we used the mean value across the replicates as the expression level of a gene.

For each DRM-candidate target pair, we computed the correlations of their activity/inactivity and expression levels across the different tissue types. We computed both value-based Pearson correlation and rank-based Spearman correlation. The statistical significance of each correlation value was evaluated by computing a p-value based on one-tailed tests using the built-in functions in R. Briefly, for Pearson correlation, the correlation values would follow a t distribution with $n-2$ degrees of freedom (where n is the number of tissue types) if the samples were drawn independently from normal distributions. The Fisher's Z transformation was used to compute the p-values. For Spearman correlation, the p-value was computed based on a procedure proposed by Hollander and Wolfe [52]. For activity signals, we considered the right tail, which means we looked for correlations significantly more positive than would be expected by chance. For inactivity signals, we considered the left tail, which means we looked for correlations significantly more negative (i.e., strong anti-correlations) than would be expected by chance. All p-values were then adjusted for multiple hypotheses testing using the Bonferroni, Holm, Benjamini-Hochberg (BH) or Benjamini-Yekutieli (BY) methods.

Differential gene expression analysis

We incorporated a module to detect differentially expressed genes in cancer samples (relative to matched normal) from RNA-Seq data. When provided with

gene expression files, our module calls NOISeq [53] when having RPKM values and DESeq [54] with raw read counts (from reads-mapping tools) to detect differentially expressed genes. Genes that are up- or down- regulated with FDR < 0.05 (with biological replicates) and FDR < 0.1 (without replicates) in cancer samples are identified and annotated in the output.

Network analysis of variants associated with genes

For each variant associated with genes, we examined their network properties in various networks. For each network, we calculated the centrality position (cumulative probability after ordering centralities of all genes increasingly) of the associated gene. If one variant is associated with multiple genes or the associated gene participates in multiple networks, the maximum cumulative probability is used as the continuous value for centrality score. Scripts are provided to calculate network centralities (Additional file 1). User can easily incorporate other networks in this analysis.

Recurrence database from whole-genome sequencing

With the increasing number of cancer samples being whole-genome sequenced, we are able to study the recurrence patterns in regulatory sequences. We analyzed somatic alterations from 570 samples of 10 cancer types to create the recurrence database [37-39], similar to the cancer recurrent gene database in cBio [55]. For each cancer type, recurrent regulatory elements, coding genes and the same-site mutations are stored as entries in the database. We also incorporated same-site recurrent regulatory variants from COSMIC (version 68) into our database. Recurrent elements are defined as identified in whole-genome sequencing and observed in at least 2 samples.

YAO FU 7/25/14 12:23 PM
Moved up [1]: One criterion to identify cancer driver genes is to examine their recurrence across multiple samples. We extended the concept to noncoding regulatory elements. Our method can detect recurrent same-site mutations, genes and regulatory elements from multiple cancer samples.

Weighted scoring scheme

1. Coding scoring scheme

Variants occurred in coding regions (GENCODE 16 for the current version; users can replace this with other GENECODE versions) are analyzed with VAT (variant annotation tool) [56]. Variants are ranked based on the following scheme (each criterion gets score 1): 1) non-synonymous; 2) premature stop; 3) is the gene under strong selection; 4) is the gene a network hub; 5) recurrent; 6) GERP score>2.

2. Noncoding scoring scheme (weighted scoring scheme)

Features used to score noncoding variants are shown in Additional file 1: Table S3. In general, features can be classified into two classes - discrete and continuous. Discrete features are binary, such as in ultra-conserved elements or not. Continuous features: 1. GERP score, 2. Motif-breaking score is the difference between germline and mutated alleles in PWMs, 3. Motif-gaining score is the sequence score difference between mutated and germline alleles, 4. Network centrality score (the cumulative probability, see 'Network analysis of variants associated with genes'). If one variant has multiple values of a particular feature (e.g. breaking multiple motifs), the largest value is used.

YAO FU 7/26/14 3:30 PM
Deleted: 2

We weighted each feature based on the mutation patterns observed in the 1000 Genomes polymorphisms. We randomly selected 10% of the 1000 Genomes

Phase 1 SNPs (~3.7M) and run through our pipeline. For each discrete feature d, we calculated the probability p_d that overlaps a natural polymorphism. Then we computed 1-Shannon entropy *(1)* as its weighted value w_d. The value ranges from 0 to 1 and is monotonically decreasing when the probability is between 0 and 0.5 (in our study, the probability of observing each feature is below 0.5).

$$w_d = 1 + p_d log_2 p_d + (1 - p_d) log_2 (1 - p_d) \quad (1)$$

$$p_d = \frac{number\ of\ polymorphisms\ with\ feature\ d}{total\ number\ of\ polymorphisms}$$

The situation is more complex for continuous features, as different feature values have different probabilities of being observed in natural polymorphisms. Thus, one weight cannot suffice for varied feature values. For a continuous feature c, which is associated with a score v_c (e.g. motif-breaking score), we calculated feature weights for each v_c. In particular, we discretized at each v_c and computed 1-Shannon entropy using *(2)*. Then we fitted a smooth curve for all v_c to obtain continuous $w_c^{v_c}$. Now, when we come to evaluate the continuous feature c for a particular variant, we calculate its weighted value (on the curve) using the actual v_c corresponding to the variant.

$$w_c^{v_c} = 1 + p_c^{\geq v_c} log_2 p_c^{\geq v_c} + \left(1 - p_c^{\geq v_c}\right) log_2 \left(1 - p_c^{\geq v_c}\right) \quad (2)$$

$$p_c^{\geq v_c} = \frac{number\ of\ polymorphisms\ with\ score \geq v_c\ for\ feature\ c}{total\ number\ of\ polymorphisms}$$

Taking 'motif-breaking score' as an example (Figure 2), for each score v, we calculated the probability of observing motif-breaking scores $\geq v$ in polymorphism data, then used *(2)* to fit the smooth function. 'nls' function in R is used to fit curves.

The criterion of 'GERP >2' has been commonly used to define conserved bases [15]. For GERP score, we chose to use sigmoid transformation to transform scores to the range 0~1. The parameters we chose make the sigmoid curve sharp at 'GERP = 2' (Figure S2). The sigmoid transformation preserves the 'GERP > 2' cut-off and makes the score continuous at the same time. We calculated *(1)* treating 'GERP > 2' as a discrete feature. Then we used $w_d * sigmoid\ transformed\ value$ to assign weighted value for each continuous GERP score.

YAO FU 7/26/14 3:29 PM
Deleted: 1

Finally, for each cancer variant, we scored it by summing up the weighted values of all its features *(3)*. If a particular feature is not observed, it is not used in the scoring. Considering the situation that some features are subsets of other features, to avoid overweighting similar features, we took into account feature dependencies when calculating the sum-up scores. As shown in Table S3, when having leaf features, the weighted values of root features are ignored. For example, when a variant occurs in sensitive regions, the score of 'in functional annotations' is not used in the sum-up. Leaf features are assumed independent. Variants ranked on top of the output are those with higher scores and are most

YAO FU 7/26/14 3:30 PM
Deleted: 2

likely to be deleterious.

$$score = \sum_{d} w_d + \sum_{c} w_c^{v_c} \quad (3)$$

Application to regulatory pathogenic and somatic cancer variants

1. Noncoding somatic recurrent variants

We obtained noncoding somatic variants form COSMIC (version 68). Recurrent variants (10,041) are defined as identified in whole-genome sequencing and observed in at least 2 samples. All other variants (1,311,389) are non-recurrent ones. After excluding variants in coding regions (GENCODE 16) and mitochondrion, there are 956 variants occurred in more than 2 samples, 8,932 variants in 2 samples and 1,305,699 non-recurrent variants. Because the same sample from different papers may have multiple ids, we also defined recurrence based on number of studies. Study-based recurrent variants also have higher scores than non-recurrent ones (Wilcoxon test: p-value = 5.2e-08).

As we know, COSMIC collects somatic alterations from diverse papers and studies. We noticed a potential artifact related to pseudogenes (Additional file 1: Figure S3) - the percentage of variants in pseudogenes increases with the number of recurrent samples or studies. After removing these variants, the trend of prediction scores persists (Additional file 1: Figure S4).

2. Noncoding somatic variants in recurrent regulatory elements

Regulatory regions mutated in more than one sample are defined as recurrent regulatory elements, such as the same TF binding motif or the same noncoding RNA. We first identified recurrent regulatory elements across multiple cancer samples. Then we classified variants either in recurrent regulatory elements or not. As recurrent regulatory elements are functional annotations, to be a fair comparison, we filtered variants in non-recurrent regulatory elements as those also in functional annotations. From 119 breast cancer samples, there are 24,022 (4,841 in recurrent elements mutated in more than 2 samples; 19,181 in elements mutated in 2 samples) and 126,217 variants in recurrent and non-recurrent regulatory elements respectively. The feature of recurrence is not considered in the weighted scoring scheme for variants in sections 1 and 2.

3. Germline pathogenic variants and matched controls

Genome locations of pathogenic regulatory variants (from HGMD [42] -1,614) and three sets of negative controls were downloaded from GWAVA [25]. The control sets – 'unmatched', 'matched TSS' and 'matched region', contain regulatory polymorphisms from 1000 Genomes with minor allele frequency ≥ 1%. 'Unmatched' control has 161,400 randomly selected variants. 'Matched TSS' control includes 16,140 variants matched for distance to the nearest TSS. 'Matched region' control has variants within 1kb around HGMD regulatory variants (5,027). Allele information for HGMD variants was obtained from HGMD database (1,527 variants). For controls, the alleles were from ENSEMBL BioMart, using reference SNP ids. We then excluded polymorphisms that were in coding

regions or used in the weighted scoring scheme, from controls ('matched region' - 4,258; 'matched TSS' - 13,861; 'unmatched' – 144,086).

We downloaded pre-calculated CADD scores for 1000 Genomes variants and extracted corresponding scores for control sets. For HGMD variants, we used the online CADD server to obtain the scores.

We compared the prediction scores of HGMD variants with three sets of controls using various measures – TPR (true positive rate), FPR (false positive rate), precision and recall. We treated HGMD as positive set and controls as negative sets. For each possible score, we draw the cut-off to make predictions and calculated - TPR = TP/(TP+FN); FPR = FP/(FP+TN); Precision = TP/(TP+FP); Recall = TP/(TP+FN). TP: true positive; FP: false positive; TN: true negative; FN: false negative. AUC score is the cumulative area under the curve of TPR and FPR.

We also tested our method with GWAS SNPs (6,604) and matched controls (66,040) from [25]. Allele information was obtained from ENSEMBL BioMart.

Framework flexibility
User data can be easily incorporated into our framework. Cancer sample-specific studies, such as histone modifications and gene expression, are especially important to evaluate variants impact. Please refer to 'Additional file 1' for usage.

Figures

Figure 1 - Schematic workflow.

SMAP consists of two modules: creation of data context and variant prioritization. We processed large scale of genomics (such as 1000 Genomes and ENCODE data) and cancer resources to create the small-scale informative data context, as shown within the dashed rectangle. The variant prioritization pipeline will take user-input cancer variants and then annotate and score them

against the data context. All features are used to annotate variants (shown in Table S2), whereas a fraction of features highlighted with red asterisk are used to score variants (details in Figure 2 and Table S3) with the weighted scoring scheme (shown in the 'variant prioritization'; details described in the main text). 'Process' contains scripts to analyze data, which can be downloaded from our website.

Figure 2 - Details of variant prioritization.

Variant prioritization step will annotate input variants and then score them using the weighted scoring scheme. Features used in the weighted scoring scheme can be classified into 'regulatory annotations', 'conservations', 'nucleotide-level analysis', 'network analysis' and 'recurrence'. 'Recurrence' feature could be detected from input cancer samples and also from 'Recurrence DB' (* means optional. Users could choose to use the 'Recurrence DB' or not). Different from other features, 'recurrence' feature of variants depends on the user-input (for example, if user only uploads one sample and chooses not to use 'Recurrence DB', then no 'Recurrence' feature will be observed for variants). Each feature is assigned with a weighted score (Material and Methods). Scores obtained from the top grey panel are called 'core scores', which is independent of user's choice (see above for 'recurrence' feature). Variants with 'recurrence' feature are assigned with additional score in the final output. The green arrow demonstrates how the score is obtained. In addition to features used in the scoring, other features are used to highlight potential interesting variants, such as variants associated with known cancer genes.

Figure 3 - Weighted scoring scheme.

A) Features used in the weighted scoring scheme. Features can be classified into two classes - discrete and continuous. Discrete features are binary, such as in ultra-conserved elements or not. For continuous features, taking 'motif-breaking score' as an example, the values would be the changes in PWMs. * only applicable when user input multiple genomes; B) We weighted each feature based on the mutation patterns observed in natural polymorphisms. Features that are frequently observed are less likely to contribute to the deleteriousness of variants and are weighted less (entropy based method, details described in Materials and Methods). For continuous feature, such as motif-breaking scores, we calculated weight for each observed value. The x-axis is the observed motif-breaking scores and y-axis is the corresponding weights. The black line show the values observed in natural polymorphisms. We then fitted a smooth curve (the red dashed line) to obtain continuous weights for all possible motif-breaking scores.

Figure 4 - Application to pathogenic germline and cancer somatic noncoding variants.

A) Score distribution of variants based on their recurrence in COSMIC. Variants are classified into three categories based on the number of recurrent samples; B) Score distribution of variants based on recurrent regulatory elements in 119 breast cancer samples. Recurrent regulatory elements are defined as elements

mutated in more than one sample, such as the same DNase1 hypersensitive site; C) Prediction scores of regulatory variants from HGMD and controls; D) ROC curves comparing HGMD variants with controls.

Tables

Table 1 - Summary of recurrence database.

Table 2 - Output for the *TERT* promoter mutation in an Medulloblastoma sample.

Additional files

Additional file 1 – Supplementary information

This file contains supplementary figures, supplementary tables and software manual.

Table 1

Cancer Type	# Samples	# Somatic Mutations (SNVs)	# Recurrent Elements | Genes | Mutations
AML	7	271~1068	1
Breast	119	1043~67347	69,140
CLL	28	522~3338	709
Liver	88	1348~25131	74,144
Lung Adeno	24	9284~297569	162,165
Lymphoma B cell	24	1502~37848	4,233
Medulloblastoma	100	44~47440	2,793
Pancreas	15	1096~14998	2,591
Pilocytic Astrocytoma	101	2~926	58
Prostate	64	1430~18225	36,327
COSMIC recurrent regulatory mutations	-	-	10,041

Table 2

Gain of motif	Associated gene	Network	Recurrence in samples	Recurrence database	Score
Motif: Ets_known10 Position: 1295223 – 1295229 Strand: + Score: 1.893 -> 5.743	*TERT* (promoter) [Cancer gene]	Protein-Protein Interaction Centrality: 0.798	2/100 Medulloblastoma samples	5/88 Liver samples; 54 COSMIC samples	2.6923
