Signaling in Networks: from Bitcoin to Biology

* I want to provide an introduction to the mechanics of Bitcoin transactions w/ I think that its an extremely interesting example of signaling in networks.

The fundamental problem that decentralized/digital currencies face is, how do we transfer "currency" between two agents.

Option #1 The old way

One book controlled by one person (exactly like a bank)

Option #2 completely decentralized

This is the double payer problem

So now we're ready to send that message.

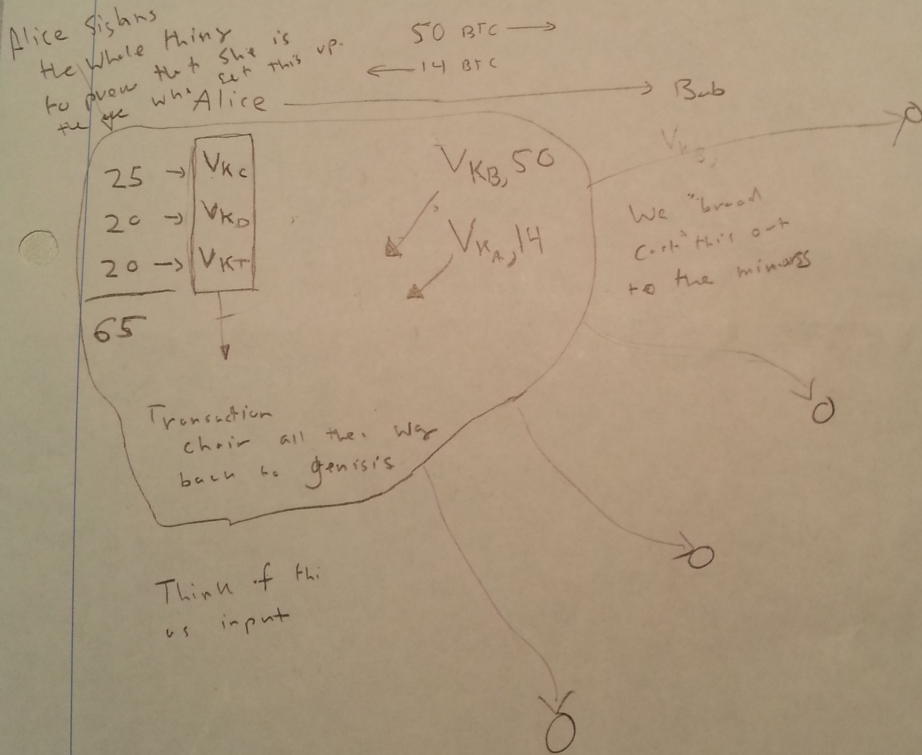

This is really fairly fool proof as long as
we don't have collisions in the hash table
 \rightarrow go into this!

ok, time to stop beating around the bush.
The 2x payor problem.

What is Bitcoin, it is something which describes
itself & its counterpart in a unified

Bitcoins are ledgers (Book of these digital signatures)

We need a decentralized time stamp

The transaction block chain.

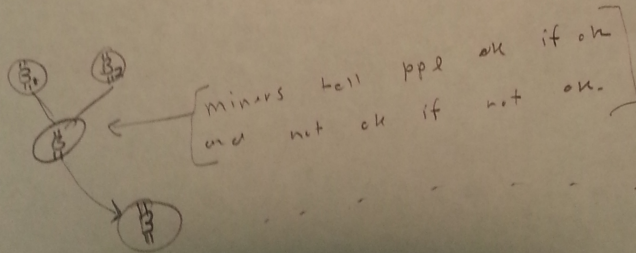

ok so for a time window we have a number of transactions.

The goal of the Miners is to reach because all Bitcoin are "independent then" + that is to check for the spenders.

This is done by forming a Transaction block it's just a list of unique Transactions in the ledger

Therefore a transaction block is a Set of legars. The goal is to get big.

Bitcoin genesis

So we have a block with many adding
transactions in same block together.

The important aspect is that

Small \rightarrow large \leftarrow adding a fee will help make this happen first
never add
Small to Small.

Then when it get to a certain level it can
be added to the genesis block chain.

The genesis chain is publicly viewable.
