# **RESPONSE LETTER**

#### **Reviewer #1**

#### -- Ref 1.0 – annotation source, false negatives --

Reviewer Comment	It seems all SNVs curated from various resources are non- synonymous as shown in Figure S1A, but this is not clearly mentioned in the Methods part of the main text. Was the basic annotation (non-synonymous or synonymous) of all SNVs from different sources done by the VAT? As we all know, not all variants from 1KG and ExAC are "benign", did you apply any filter to minimize the potential false negatives (e.g., in silico prediction tools)?
Author Response	We would first like to thank the reviewer for taking to time to carefully read through our study, and we also thank the reviewer for valuable suggestions on how we may improve this work. In the revised version of the manuscript, we now specify that we exclusively look at non-synonymous SNVs. The reviewer has correctly pointed out that the annotations of coding SNVs were obtained using VAT. Furthermore, we agree with the reviewer that not all variants from 1KG and ExAC are necessarily benign. In an effort to deal with this, we have removed any known disease-associated variants (HGMD and TCGA), that were initially present in the 1KG and ExAC datasets.
Excerpt From Revised Manuscript	"We utilized a comprehensive catalogue of non-synonymous SNVs from various resourcesIn order to avoid redundancy and false positive call sets, we removed HGMD variants present in the 1000 genome and ExAC SNV datasets. In addition, we also removed known TCGA variants present in the original ExAC SNV datasets."

# -- Ref 1.4 -- variants with unknown significance --

Reviewer	The results are interesting. However, I was looking	
Comment	forward to seeing how the workflow was applied to variants	
	of unknown significance to help classify/predict their	
	impact, e.g., using a certain value of $\Delta F$ as a threshold.	
	This would be extremely valuable and useful for other	
	investigators.	
Author	We agree that greater value may be derived from $\Delta F$ if a specific	
Response	threshold may be used when making predictions on newly discovered	
-	SNVs. In order to rigorously define a $\Delta F$ that may optimally be used to	
	distinguish between deleterious and benign SNVs, we have taken the	
	empirical approach of jointly analyzing the distributions of $\Delta F$ scores for	
	HGMD (disease-associated) and SNVs from ExAC (presumably	
	benign) The details and results of this analysis are now included within	
	the Supplementary Materials (Supplementary text S3)	
Excernt From	The deleteriousness of an SNV is a continuous variable, and indeed, this is reflected in the	
Revised Manuscript	continuous nature of $\Delta F$ values. However, there is still considerable value in applying a binary	
1	classification scheme to newly discovered SNVs, which may be predicted to be benign or	
	deleterious.	
	As discussed in the results of the main text, disease-associated SNVs from HGMD generally	CXI
	induce more negative $\Delta F$ values relative to benign SNVs. Given a newly discovered SNV, is	12.
	there a specific $\Delta F$ threshold that may optimally be used to classify SNVs as beingn or delatations 2. We address this issue ampirically by antimizing a function $f(x)$ defined by two	
	distributions (Supplementary figure S5)	
	distributions (Supplementary righter 55)	
	f(x) = h(x) + e(x)	
	Let $\Delta F_{HGMD}$ denote the distribution of $\Delta F$ scores induced by HGMD SNVs. $h(x)$ is defined to be	
	the difference between the fraction of $\Delta F_{HGMD}$ scores less than x ( <i>fract</i> [ $\Delta F_{HGMD} < x$ ]) and the	· · · · · ·
	fraction of $\Delta F_{HGMD}$ scores greater than x ( <i>fract</i> [ $\Delta F_{HGMD} > x$ ]):	-
	$h(x) = fract[\Delta F_{HGMD} < x]) - fract[\Delta F_{HGMD} > x])$	
	With $\Delta F_{ExAC}$ similarly defined for the distribution of $\Delta F$ values associated with ExAC SNVs:	

$e(x) = fract[\Delta F_{ExAC} > x]) - fract[\Delta F_{ExAC} < x])$
Note that, in building the distribution of $\Delta F_{ExAC}$ values, a random sample of ExAC SNVs was chosen in order to match the number of SNVs in the $\Delta F_{HGMD}$ distribution. The <i>x</i> that maximizes the function $f(x)$ is taken as the $\Delta F$ threshold for predicting whether a newly discovered SNV is deleterious or benign. Using this approach, we find that this ideal threshold takes a value of $\Delta F = -1.221$ .

۵

### -- Ref 1.5 – Clarification regarding p-value --

Reviewer	In the last paragraph of Results: Differential effects of		
Comment	benign and disease-associated SNVs on $\Delta F$ profiles, you		
	stated that "In addition, disease-associated SNVs (from		
	HGMD) result in similar frustration changes between core		
	and surface residues (p-value < 2e-16 from two-sample		
	Wilcoxon test) (Figure 2C)." The frustration changes are		
	similar between core and surface residues, but the p-value		
	looks so significant (2e-16). Please confirm.		
Author	We agree with reviewer that $\Delta F$ values are similar for the above-		
Response	mentioned comparisons. Unfortunately, the p-value statement was		
•	misplaced in the original text, which was intended for the next		
	statement (describing the comparison between HGMD core and		
	1KG/EXAC core residues). This has now been corrected.		
Excerpt From	"However, SNVs from HGMD that impact minimally frustrated core residues induce stronger		
Revised Manuscript	perturbations than benign SNVs influencing minimally frustrated core residues ( <i>p</i> -value $< 2e$ -16		

## -- Ref 1.6 – Clarification regarding p-value --

Reviewer	In the last paragraph of Results: Differential effects of
Comment	SNVs on oncogenes and tumor-suppressor genes, you stated
	that "We observed that SNVs affecting TSGs induce stronger
	perturbations in minimally frustrated core residues
	relative to surface residues (p-value = 8.15e-2 from two-
	sample Wilcoxon test) (Figure 6A)." It seems the
	difference was not significant (p = 0.08), so were you
	able to make this conclusion?
Author	Reviewer correctly points out that two-sided Wilcoxon test p-value is
Response	higher than 0.05 However, both two-sided ks test (p-value = 0.004765)
•	and one-sided Wilcoxon test (p-value = $0.04259$ ) indicate statistically
	significant difference between TSG and Oncogene frustration change
	distribution
	distribution.
Excerpt From	"We observed that SNVs affecting TSGs induce stronger perturbations in minimally frustrated
Revised Manuscript	core residues relative to surface residues ( <i>p-value</i> = 4.259e-2 from two-sample one-sided
	Wilcoxon test) (Figure 6A)."

# -- Ref 1.7 – Fixing typographical & grammatical errors --

Reviewer	There are minor misspellings or formatting errors: (a) in
Comment	Methods: SNV Datasets, "Human Genome Mutational Database"
	should be "Human Gene Mutation Database"; (b) in Methods:

### -- Ref 2.0 – Accessibility of the method --

Reviewer Comment	How can your method be accessed / used by other scientists who want to analyse their data? I don't find a link to a website / download archive or similar.		
Author Response	We would first like to thank the reviewer for taking to time to carefully read through our study, as well as providing valuable suggestions on how we may improve this work.		
	With respect to source code, we have now provided this content as a public resource on github: <a href="https://github.com/SK/2014/frstn">https://github.com/SK/2014/frstn</a>		

### -- Ref 2.1 – Filtering datasets for comparisons--

Reviewer	Concerning the datasets used for benign and disease-
Comment	causing SNVs. Which variants from HGMD were included? As
	far as I know, there are different categories of variants
	in HGMD: DM=Disease causing (pathological) mutation, DM? =
	Likely disease causing (likely pathological) mutation,
	DP=Disease associated polymorphism, DFP=Disease associated
	polymorphism with additional supporting functional

		-
	evidence, FTV=Frameshift or truncating variant with no	
	disease association reported yet, FP=Polymorphism	
	affecting the structure, function or expression of a gene	
	but with no disease association reported vet. In order to	
	create a testset of "disease mutations" all categories	
	create a cestset of disease mutations, all categories	
	except for DM should be avoided in order to make sure that	
	the test data has the highest possible quality. Variants	
	which were found in association studies are not suitable	
	to go into a test set of disease mutations, since there is	
	only an association between the variant and the disease	
	and not a proven functional link.	
	The same applies for the data taken from 1000G and ExAC:	
	Although these are generally denoted "common", there are	
	aignificant differences in the geneture frequencies and	
	significant differences in the genotype frequencies and	
	MAFS of the variants. Especially in the EXAC data,	
	variants which are associated with a specific clinical	
	phenotype might be included. Moreover, there are also	
	variants from TCGA (which went into your disease-variant	
	set) included in ExAC.Did you chose a certain threshold	
	for genotype frequency or MAF, above which you considered	
	a 1000G / ExAC variant as common enough to be	
	harmless/henign? If was this should go to the	
	narmiess/benight if yes, this should go to the	
	paper/supprement, if no, you should restrict the dataset	
	to a somewhat smaller subset of variants, according to a	
	sensible threshold. Moreover, did you cross-check if there	
	are HGMD variants, which are also present in the	
	1000G/ExAC data? This also happened in the past.	
Author	We thank the reviewer for these valuable suggestions. We have	
Response	undeted our detected such that:	
Ксэронэс	upualeu our ualasets such that.	
	1) we only keep HGMD variants with the status label "DM";	
	2) we have removed HGMD and TCGA variants present in	
	EvAC: and	
	EXAC, and	
	3) we have removed HGMD variants in the 1000 Genomes	
	dataset	
		$\searrow$
	When this filtering is performed, a very small fraction of SNVs	X
	were removed from our analysis and we note that this filtering	
	which have the state of the sta	1
	did not neavily affect our main results. However, we have	
	updated our figures and p-values to reflect this pre-processing.	
	$M_{\rm e}$ applied a MAE threaded of 0 E0/ to distinguish between res.	
	we applied a MAF threshold of 0.5% to distinguish between rare	
	and common variants. This information is now provided in our	
	undated Methods section	
E

	variants present in the original ExAC SNV datasets."	
	"Furthermore, we investigated the differential influence of common and rare mutations, where	
	SNVs with minor allele frequency (MAF) less than or equal to 0.5% were considered to be rare	

mart.

### -- Ref 2.2 – Usefulness of the method --

		-
Reviewer	To underline the usefulness of your method, which is, as	
Comment	said in your manuscript, to meet a "growing and urgent	
	need to evaluate the potential effects of low-allele-	
	frequency variants in unbiased ways using high-throughput	
	methodologies". I miss some extra calculations /	
	benchmarking There are methods existing in order to	
	evaluate notential effects of low-allele-frequency	
	warianta in unbiaged wave (CIET DeluDhen?	
	Valiants in unbiased ways (Siri, Polyrnenz,	
	Mutationraster, and many others). I would like to see now	
	exactly your method adds up to this. Is the additional	
	information gained from structural analysis really an	
	advantage over existing methods? If you could show this,	
	this would surely be an argument for people to use and	
	cite your method. If they don't know if your method is	
	really helpful, they will maybe not even try it, since	
	analysis of high-throughput data is (already) time-	
	intensive. One could for example create a small set of	
	variants and analyse these with one or two of the "common"	
	tools to predict the deleteriousness of SNVs (e a	
	PolyPhen2 and MutationTaster2 since these are generally	
	considered the most accurate ones) and then check if there	
	considered the most accurate ones) and then theck if there	
	are disease variants predicted as narmitess by these	
	tools (i.e. false negative) which are then correctly seen	
	as locally maximal frustrated by your method. Or any other	
	way how it can be shown that the method is indeed useful	
	for the analysis of high-throughput data (e.g. compare	
	with other existing "structural prediction" tools, if	
	those exist).

"We selected a smaller set variant mapped onto PDB structure, which has at least one HGMD
and at least one ExAC non-synonymous SNVs. Subsequently, we identified instances where
HGMD variants were predicted to be benign by polyphen2 or SIFT (False negative cases) but
delta frustration metric indicates significant increase in frustration level upon mutation. We
observed that 10% of the variants in this smaller set of variants were annotated as benign by
polyphen2. Similarly, SIFT incorrectly predicted 13.7% of these HGMD variants to be not
damaging. Furthermore, we analyzed the delta frustration values for variants in this dataset.
Applying the delta frustration threshold described earlier, we observed that 38% of the miss-
annotated variants had significantly large frustration change indicating their potential
deleteriousness. Furthermore, we also identified that ~46% of SIFT annotated false negative
variants had large delta frustration values associated with them. We also highlight an example
by plotting linear diagram for such case in the supplementary Figure S6."

#### -- Ref 2.3 – Method run time scale --

Reviewer	How long would it take to analyse let's say 10,000 SNVs?	
Comment	As this is more or less the dimension which goes along	
	with HT-sequencing.	
Author	The reviewer has raised a good question of practical interest. We	
Response	ran our pipeline on 10,000 SNVs, and it took ~2.5 hours to map	
	these variants to PDB structures. In total, we mapped 20% of	_
	these SNVs onto three-dimensional structures. Further,	
	generating the mutated protein model and frustration calculations	
	for the structurally mapped variants took ~26 hours.

Reviewer Comment	Concerning Fig. 1: Residues are not numbered. In the text, you talk about ILE in pos. 31 which is exchanged to TYR. In the figure legend, you say that TRP is changed to TYR. In the picture, there is TRP highlighted as well as TYR,	
	but the native and mutated structure (at least the part	
	snown) differ in more chan just chis one residue. This	
	confuses me and should be clarified.	
Author	We thank the reviewer for pointing out this inconsistency. We	
Response	have fixed the text in our methods section to remove this	
	ambiguity.

Revised Manuscript	locus within ubiquitin (PDB ID 1UBO) with a tyrosine."	

### -- Ref 2.4 –Typographical error --

#### -- Ref 2.5 – Violin plot description in figure legends --

Reviewer	Concerning the Fig. 2-6 (violin plots): The figure legends		
Comment	do not say what the white dots and the vertical lines		
	stand for. Mean? Median? Standard deviation? Range? This		
	should be explained. Which difference between delta F is		
	regarded significant (concerning differences in delta F		
	"core" between bening SNVs and disease-causing SNVs)?		
Author	We agree that some clarifications were needed here. In the revised manuscript,		
Response	we explain the meanings of white dots and vertical lines within the updated		
	figure legends. Comparison of $\Delta F$ distributions for the ExAC core SNVs and		
	HGMD core SNVs point to statistically significant differences (p-value < 2e-		
	16 using a two-sided Wilcoxon test). Furthermore, this observation was also		
	true for comparisons involving 1000 Genomes core SNVs and HGMD core		
	SNVs.		
Excerpt From	"The white dots, the black boxes and vertical lines represents the medians, interquartile ranges,		
Revised Manuscript	and 95% confidence intervals of $\Delta F$ distributions, respectively"		

#### -- Ref 2.6 - cutoff for common/rare differentiation --

Reviewer	Fig. 3: Which MAF separates "common" from "rare" SNVs?
Comment	
Author	We applied a MAF threshold of 0.005 to distinguish between rare (MAF
Response	<=0.005) and common variants. This previously missing information
	has now been incorporated into the text.
Excerpt From	"Furthermore, we investigated the differential influence of common and rare mutations, where
Revised Manuscript	SNVs with minor allele frequency (MAF) less than or equal to 0.5% were considered to be rare
	mutations. SNVs were otherwise classified as common. "

#### -- Ref 2.7 – Spacing error --

Reviewer	Very minor point: Sometimes, spaces are missing (e.g. p.3
Comment	1.21/1.37). Re-check for this.
Author	We thank the reviewer for pointing this out. We have fixed this formatting
Response	error in the updated version of the manuscript.

### -- Ref 3.1 – Regarding limitation of method --

Reviewer	The main rationale for the paper put forward by the			
Comment	authors is rapidly growing number of rare variants coming			
	from individual genomes sequencing projects and the need			
	for new methods to infer potential functional associations			
	of such variants. However, the results presented in this			

	<pre>work clearly underscore main limitation of all structure- based methods: scarcity of high-resolution 3D protein structures and low PDB mapping coverage makes them less useful compared to more common sequence-based methods. In fact, the fraction of successfully PDB-mapped variants from ExAC database reported by the authors is below 2% (Supporting Information). This makes method's potential contribution to large scale interpretation of rare and unknown significance variants rather questionable. More general estimates usually agree upon less than 10% of all known human proteins covered by PDB, still too few. Unfortunately, there is no evidence that this coverage would increase significantly in the near future. Also, PDB is highly biased towards representing a subset of all known protein folds/domains and this bias keeps increasing, not diminishing. I would recommend either removing or significantly toning down all claims about potential applicability of the method towards large-scale human variant interpretation, specifically from the Abstract and Introduction.</pre>	
Author Response	We thank the reviewer for pointing out these issues. We agree that there are inherent limitations in structure-based methods as a result of relatively low coverage across the human proteome. However, there has been a persistent increase in the structural coverage due to improvements in three-dimensional structure determination. We have highlighted this gradual increase in protein structural space in a recent review (pubmedID:26658741). In addition, we anticipate further increases in the structural coverage due to cryo-Electron microscopy. The advent of cryo-EM has made it possible to resolve the three- dimensional structures of relatively large protein/protein-complexes, which were unfathomable a decade ago. Finally, the growing systems-level view of protein biology (e.g., protein-protein interaction networks) may help to broaden the relevance of the limited number of cases in which SNVs lie within known structures (discussed in excerpt below). However, the limited coverage of SNVs in structures persists as a major challenge, so we have also provided a discussion of this challenge in the updated manuscript	
Excerpt From Revised Manuscript	<ul> <li>Excerpt from Introduction:         <ul> <li>Though the majority of disease-causing variants lie in non-coding regions of the genome, many of them lie in protein-coding genes. Furthermore, only a limited fraction of non-synonymous SNVs may be mapped to known protein structures. However, immense progress has been made in resolving the three-dimensional structure of many proteins over the last several decades (13)</li> </ul> </li> <li>Excerpt from Discussion:         <ul> <li>"Historically, the relative scarcity of genomic variation and structural data have presented challenges in variant interpretation, in that only a small pool of SNVs may be mapped to resolved structures Howvere, limited mapping coverage persists as a major challenge, a number of recent trends may partially help to mitigate this issue. Significant improvements in crystallographic protocols have enabled near-exponential growth in deposited X-ray structures in the PDB (10). Furthermore, cryo-EM is opening entirely new avenues for revealing the architectures of many proteins which were previously elusive to crystallography, which is expected to expand the structurally-resolved proteome (59). Finally, systems-level descriptions of cellular phenomena provide a more complete understanding of context in which proteins operate. Specifically, there is a growing understanding of protein-protein interaction networks and the role of resolved structures therein (60). As such, inferring how a given SNV affects a particular structure is by no means limited to predictions regarding that protein alone – the</li> </ul></li></ul>	

protein's tight associations with other molecules may greatly broaden the scope of how that SNV influences more global cellular phenomena. For instance, the functional consequences of
an SNV within a central hub protein of a network may effectively be propagated. "

#### -- Ref 3.2 - variant statistics and semi-balanced variants --

Reviewer	Another known issue is strong annotation disparity between	
Comment	known Mendelian disease mutations (e.g. HGMD disease	
	variants) and other variants: most of HGMD mutations are	
	reported in a small subset of proteins, while majority of	
	the proteins only have fewer and mostly benign or unknown	
	when performing comparisons between the two functional	
	classes of variants. In case of PDB-mapped variants, such	
	annotation bias might have been alleviated to some extent	
	by the PDB intrinsic bias (mentioned above, skews PDB $\&$	
	HGMD data towards the same proteins) but it requires	
	further investigation. Authors should present statistics	
	for the number of unique proteins and the distribution of	
	datasets. They should also attempt to perform their	
	analysis on a (semi-)balanced set(s) of variants, using	
	sets of proteins where both disease and neutral mutations	
	are present. See Grimm et al. (2015) Human Mut. 36:513-523	
	for an example of such balanced sets and trends analysis.	
Author	We thank the reviewer for these observations and we agree that some	
Response	analyses and discussion should be devoted to exploring these points.	
	As such, new analyses and text have been integrated into the	
	Discussion and Supplementary section of the revised manuscript. We	
	have also performed our analysis on a semi-balanced set of variants	
	(as proposed by the reviewer), and we report the results of this analysis	
	in the supplementary information. Overall the trends were very much	
	consistent with our prior analyses. However, the new dataset lacks	
	statistical significance, potentially as a result of the fact that it is	
	considerably smaller dataset. The details of these analyses are	
En comt Encor	provided in the excerpt below.	
Revised Manuscript	"Considerable annotation disparities exist between HGMD variants and variants taken from	
	1000 Genomes and ExAC, raising the possibility of bias between the evaluated structure	
	datasets. The sets of proteins evaluated in the context of HGMD variants may thus be	
	considerably different from those of 1000 Genomes/ExAC SNVs, thereby making direct	.56
	comparisons difficult. Finally, some protein structures may be over-represented in any given	171
	dataset. To control for these effects, we first identify a non-redundant set of unique proteins	- 1 Mat
	within each dataset. Specifically, the non-redundant set is constructed by ensuring that no	50:1.1
	protein within the set shares more than 90% sequence identity with any other protein in the set.	ښ۴۳
	We find that there are 618, 907, and 303 distinct proteins within the set of high-resolution	-
	structures impacted by 1000 Genomes, ExAC, and HGMD SNVs, respectively. Distributions	
	delineating the number of SNVs within these unique (i.e., non-redundant) protein sets are given	
	in Supp. Fig. S2-S4."	

# -- Ref 3.3 – SNV frequency summary --

Reviewer Comment	Please, provide complete breakdown for the raw numbers of SNVs in each subcategory analyzed for the data presented						
	in the Figur	res: Core/Sur	face, Cor	e/Surface/	Common	/Rare,	
	etc.
