## Abstract

288 words

Functional genomics experiments provide information about genomic activities such as gene expression under different conditions, which are not tied to an individual's genotype. However sharing of such data raises privacy concerns due to quantifications being tagged with individual's variants. Although, progressive summarization such as signal profiles is believed to reduce private information leakage, they also reduced the utility and amount of the open-access data. On the other hand, while granting special permission to access the raw data can remedy privacy concern, open access to such large amounts of data accelerates biomedical research and increases reproducibility. Current genome privacy studies lack a systematic quantification of the amount of leakage in raw functional genomics data and privacy-preserving solutions in an open-access data-sharing mode. Here we introduce information theory-based measures to systematically quantify the amount of sensitive information in raw reads of different functional genomics assays at different sequencing depths. We showed that high depth experiments such as Hi-C provide accurate genotyping that lead to large privacy leaks. Counter intuitively, noisy and partial genotypes from low depth experiments such as ChIP-Seq and single-cell RNA-Seq can be used as strong quasi-identifiers for re-identification purposes through linking attacks. In order to solve the dilemma between open access vs. privacy leak, we propose a file formatting system that enables sharing of large amount of data while protecting individuals sensitive information and preserving the utility of the data. Such file format manipulation can be used in different levels to achieve different levels of privacy, hence provides a differential-privacy like framework.

# 1 Introduction

With the decreasing cost of DNA sequencing technologies, the number and the size of the available genomic data have exponentially increased and become available to a wider group of audiences such as hospitals, research institutions and individuals [1]. In turn, privacy of individuals has become an important aspect of biomedical data science [2, 3] as availability of genetic information gives rise to privacy concerns such that genetic predisposition to diseases may bias insurance companies [4] or create unlawful discrimination by employers.

Early genomic privacy studies focused on identification of individuals in a mixture by using phenotype-genotype association [5, 6]. These revealed that private information of an individual such as participation to a drug-abuse study [5, 6] can be revealed. With the increase of large-scale genomic projects such as Personal Genome Project (PGP) [7] or recreational/direct-to-consumer genomic databases, researchers showed that multiple datasets can be linked together to infer sensitive information such as participant's surnames [8] or addresses [9]. Such cross-referencing relies on quasi-identifiers, which are pieces of information that are not unique identifiers by themselves, but are well correlated with unique identifiers or can be unique identifiers when combined with other quasi-identifiers [10].

Functional genomics experiments provide a wealth of information on genomic activities related to developmental stages or diseases that are essential for personalized medicine. These are large-scale, high-throughput assays to quantify transcription (RNA-Seq) [11], epigenetic regulation (ChIP-Seq) [12] or 3D organization of genome (Hi-C) [13] in a genome-wide fashion under different conditions (e.g. samples from patients and healthy individuals). Inferring biological information from functional genomics experiments is a several steps procedure, in which progressive summarization of the data from raw sequencing reads to the gene quantifications, TF binding peaks or chromatin interaction matrices is performed. **Although activities of functional genome are not**

necessarily tied to an individual's genotype, quantification of such activities is derived from the biosamples that belong to individuals, hence they are tagged with individual's variants. Public sharing of such raw data raises privacy concerns. To be able to share high utility data while preserving individuals' sensitive information, it is essential to determine a "set point", after which trade-off between the utility of the data and the privacy risk is balanced. A hurdle in determining the "set point" is the lack of systematic quantification of private information leakage from the functional genomics data. Figure 1) summarizes the processing steps of functional genomics experiments with how summarization decreases the risk of privacy while greatly decreasing the amount of sharing and the utility of the data. In detail, functional genomics data analysis starts with the generation of DNA/RNA sequencing reads that are stored in special file formats called fastq [14]. These files are large in size ranging from 5 GB up to 60 GB depending on the purpose of the experiment. They are then mapped to human reference genome and these mapped reads are stored in compressed binary file types called BAM [15]. Further summarization of the mapped reads (such as signal profiles or gene expression quantification) still allows researchers to make accurate biological conclusions, while providing further data reduction of a ~20 fold. Although overall aggregation and averaging reduces biological information, private information leakage also decreases (Figure 1).

In particular, BAM files are of great interest due to the large amount of biological data they provide as they constitute the most important input of majority of genome annotation pipelines. On the other hand, these files contain sequence information of the individual that may leak sensitive data. Depending on the depth of the functional genomics experiment, raw reads can be used to identify the private SNPs, small indels, and structural variants. However, current policies related to public sharing of the BAM files are somewhat ad-hoc. For example, for the genome of HeLa cell line, the raw reads from Hi-C experiments require special access, while reads from ChIP-Seq and RNA-Seq experiments are publicly available [19]. That is, reads from the experiments

that do not require substantial depth are sometimes considered to be safe to share without privacy concerns owing to partial and biased sequencing, although it is not clear if these reads are leakage free. Although private information leakage from summary level functional genomics data are quantified previously [?, ?] the lack of a systematic quantification of private data leakage from BAM files makes it difficult for biomedical data sharing policy makers to protect individual's sensitive information in a consistent fashion. File formats such as CRAM is developed to remedy the ever increasing amount of data [?]. Although CRAM greatly reduces the size of the data in BAM files, there is still privacy leaks due to the containment of the sequence of the reads [?]. MRF was introduced as an alternative to CRAM, where keeping the sequence of reads is optional [?]. This does not only reduces the size of the data, but also makes it hard to genotype the individuals from the information in these files. However, private information leak is not entirely removed from MRF files, as one can still infer deletions from the information in these files. Moreover, current quantification pipelines used for gene expression analysis as well as the peak calling softwares were not designed to take MRF file format as inputs.

On the flip side of the coin is the utility of the mapped reads (BAM files) and challenges related to dealing with private data. Accession to private data requires use agreements that have expiration dates and a tremendous amount of bureaucracy connected to it. Moreover, any secondary data product becomes private and cannot be distributed. Problems associated with the distribution of secondary data products from private biomedical data is exacerbated due to large file sizes. For example, genome annotations that are derived from private functional genomics data require establishment of their own databases. However, since such annotations are derived from private data, establishment and distribution of these databases require extra levels of privacy related bureaucracy. Another example to the challenges associated with private data is that big consortia such as ENCODE [20], TCGA [21] or GTEx [22] fund multiple research institutions and enable a collaborative working environment through dedicated phone calls and meetings. In turn, participants have

to go through required access procedures with their institutions. Otherwise communication based on private data is prohibited according to data use agreements. Moreover, when multiple institutions have required access to the same data, they still cannot exchange files with each other. These challenges create a bottleneck and hinder the progress of important biomedical findings. Open data helps the advancement of biomedical data science not only with the easy access to the data, but also helping with the speedy assesment of tools and methods and in turn reproducibility. Funding agencies and research organizations are increasingly supporting new means of data sharing and new requirements for making data publicly available while preserving the participant's privacy [23]. In an attempt to consider both sides of the coin, we ask the questions of how much information is enough information to identify individuals and how we can protect the sensitive information with minimum loss of utility in a publicly data sharing mode. To this end, we derive novel information theory-based measures and apply these measures to quantify the amount of leaked information in 24 functional genomic assays from ENCODE [20] at varying coverages. Based on our findings, we develop new file formats that allow the public sharing of read alignments of functional genomics experiments while protecting the sensitive information as well as minimizing the amount of private data that requires special access and storage. **Our file format manipulation system achieves different levels of privacy vs. utility balance with an adjustable parameter and provides a differential-privacy like framework.**

In this study, we use NA12878 as a case example and her 1000 genomes [24] genotypes as gold standard genotypes. We sample reads from the sequencing data of functional genomics experiments at increasing coverages and detect SNVs and indels using Genome Analysis Toolkit (GATK) best practices recommendations [25, 26]. We propose a new metric for quantifying the amount of information that can be obtained from sequencing data with respect to the gold standard. We next present a simple and practical instantiation of a linking attack with the assumption of adversaries accessing increasing amount of the seqencing data. We show that individuals are vulnerable to

identifications even at small coverages of sequencing data. We further show that with summation of reads from functional genomics experiments and imputation through linkage disequilibrium, the leaked number of variants can reach the total number of variants in an individual’s genome. We then provide a theoretical framework where the amount of leaked information can be estimated from depth and breadth of the coverage as well as the bias of the experiments. Finally, we focus on ways to publicly share alignment data without comprimizing individual’s sensitive information. We propose privacy enhancing file formats that hide variant information, are compressed and have minimum amount of utility loss.

## 2 Results

### 2.1 Information Theory to quantify private information in an individual’s genome

An individual’s genome can be represented as a set of variants. Each variant is composed of the chromosome it belongs to, location on that chromosome, the alternative allele and its corresponding genotype. Let  $S = \{s_1, s_2, \dots, s_i, \dots, s_N\}$  be the set of variants, then each variant can be represented as  $s_i = \{v_i, g_i\}$ , where  $v_i$  consists of the location and alternative allele information and  $g_i$  denotes the genotype of the variant as 1 for heterozygous variant and 2 for homozygous variant. We can then calculate the naive self-information of  $S$  in bits as

$$h(S) = - \sum_{i=1}^{i=N} \log_2(p(s_i)). \quad (1)$$

In eq. 1  $N$  is the total number of variants in an individual’s genome,  $p(s_i) = n_i/n_T$  is the genotype frequency, in which  $n_i$  is the number of individuals with variant  $s_i = \{v_i, g_i\}$  and  $n_T$  is the total number of individuals in the panel. Note that we denote  $h(S)$  as “naive” information, because it is an estimate of the real information in a situation where the population that the individual belongs to

is not known and the number of individuals are finite. Eq.1 holds only if variants are independent of each other, which is not the case due to the correlation between variants in linkage disequilibrium (LD). In theory, the population that the individual belongs to can easily be predicted by using a few variants. However, from an adversary's perspective, this will add one more layer of calculation, i.e computational and time cost to identification attack. Eq.1 also an estimate to the information when we consider all the individuals in the world (i.e  $\lim_{n_t \rightarrow \infty} h(S)$ ).

To be able to understand whether naive information is a good estimate, we first calculate the information with the consideration of LD scores taken from the European population of HapMap project [27]. LD scores are pairwise correlations between variants, which we consider as the prior information on the existence of a variant given other variants in the same LD block exist in a genome. Then the information with LD consideration is calculated as

$$h^{LD}(S) = - \sum_{i=1}^{i=N} (1 - mLD(s_i, s_j)) h(s_i) \quad (2)$$

$LD(s_i, s_j)$  is the maximum LD correlation of variant  $s_i$  such that  $mLD(s_i, s_j) = \max_{i \neq j, j \in (1, \dots, N)} LD(s_i, s_j)$ , where  $mLD(s_i, s_j) \neq mLD(s_j, s_i)$ .

Figure 2a shows a negligible difference between the naive information and information with LD consideration for NA12878 genome. To understand the lack of difference better, we calculate the self-information of each variant in an LD block with and without LD consideration. We show that highly informative variants do not exhibit any difference due to the low LD correlations (Figure 2b). We further show that the number of variants that have difference between information with and without LD consideration is small compared to highly informative variants having low LD correlations on average.

We then estimate the information when the population size is infinite [28]. We sample fractions in the order of 10%, 20%,..., 100% individuals from the 1000 genomes phase I panel (total of 2504 individuals) and calculate the information using the sampled distribution of genotypes. We repeat this calculation for 100 times and calculate the mean information for each sampled fraction. The relationship between the inverse of the sample fraction and the information fits best to a power function with two terms ( $y = ax^b + c$ ,  $R = 0.99$ ). The  $y$ -intercept ( $c$ ) of the curve is the extrapolation of information when the population size goes to infinity ( $1/\infty = 0$ , Figure 2c). We again found a negligible difference between the naive information and the information when the population size is infinite (Figure 2a). The information is also calculated by starting from a single individual and adding individuals one by one to the population (SI Figure 1). These individuals are simulated using the genotype frequencies in the 1000 genomes panel and the LD information from HapMap project (see SI methods). Both the information calculation and the  $KL$ -divergence between different size populations show that as the size of the population increases, the difference in the information decreases and eventually becomes negligible (SI Figure 1a-b)

In summary, calculations above show that the naive information can be an accurate approximate to the private information content of an individual's genome when the individual's population is not known and the population size is bound by the number of individuals in 1000 genomes panel due to the relationship of information at  $n \rightarrow \infty \geq \text{naive information} \geq \text{information with LD}$  (Figure 2a). That is, an adversary with no prior knowledge on the population of the sample and limited number of individuals in a known genotype panel can accurately approximate the private information in the sample.

## 2.2 Information Theory to quantify private information leakage in functional genomics data

In an effort to understand the relationship between the leaked information and the coverage as well as for a fair comparison,  $k$  amount of reads were sampled from the 24 different functional genomic experiments and from WGS and WES data of NA12878 (see SI Table 1). Genome Analysis Tool Kit (GATK) is used to call SNVs and indels with the parameters and filtering suggested in GATK best practices [25, 26]. The genotypes in 1000 genomes panel for NA1278 is used as the gold standard. We use “naive” pointwise mutual information (pmi) as a measure to quantify the association between the gold standard and the called variants. If  $S^G = \{s_1^*, \dots, s_i^*, \dots, s_M^*\}$  is the set of variants from the gold standard and  $S^F(k) = \{s_1, \dots, s_i, \dots, s_M\}$  is the set of variants called from the  $k$  reads of a functional genomics experiment, then the set  $A = S^G \cap S^F(k)$  contains the variants that are called and are in the gold standard set. If  $A = \{a_1, \dots, a_i, \dots, a_T\}$ , then

$$pmi(S^G; S^F(k)) = - \sum_{i=1}^{i=T} \log_2(p(a_i)) \quad (3)$$

We then add  $k$  more reads to the sampled reads and repeat the calculation. This procedure is repeated till we deplete all the reads of a functional genomics experiment. Overall process is depicted in Figure 2e.

## 2.3 Private information leakage in 24 functional genomics experiment at different coverages

The pmi values for 24 functional genomics experiments are calculated at different coverages. These experiments involve whole genome approaches such as Hi-C, transcriptome-wide assays such as RNA-Seq and targeted assays such as ChIP-Seq of histone modifications and transcription factor binding. In addition, the pmi is also calculated for WGS, WES, and SNP-ChIP for

comparison (Figure 3).

As expected Hi-C data contains almost as much information as WGS and more information than SNP ChIP arrays. WGS data contains more information than Hi-C in the beginning of the sampling process. As we sample nucleotides that are between around 1.1 and 10 billion bps, the information content of Hi-C surpasses the WGS data (Figure 3a). We speculate that this is due to better genotyping quality of the genomics regions that are in spatial proximity, as Hi-C has a bias of sequencing more reads from those regions. As expected, we cannot infer as much information from ChIP-Seq reads (Figure 3b). However, surprisingly many of the ChIP-Seq assays such as the ones targeting CTCF and RNAPII contain a great amount of information at low coverages. Furthermore, comparison between WES and different RNA-Seq experiments show that none of the RNA-Seq experiments contain as much information as WES, which is due to the fact that RNA-Seq captures reads only from expressed genes in a given cell (Figure 3c). The unexpected observation is that more information can be inferred from polyA RNA-Seq data at low coverages compared to WES and total RNA-Seq. To be able to make a fair comparison between all these assays, we calculate the mean pointwise mutual information per bp depicted in Figure 3d  $(\frac{\sum pmi(S^F(k); S^G)/k}{(\text{number of samples})})$ . We found that Hi-C experiments and ChIP-Seq experiments targeting the transcription factor HDGF provide more genotyping information per basepair compared to WGS data (Figure 3d).

## 2.4 Genotyping accuracy

In light of the above findings, in which genotyping can be done using low depth, biased functional genomics experiments, we assess the accuracy of genotyping by calculating the false discovery rate at different coverages. This also measures how much noise that each assay captures. The false discovery rate is defined as the ratio between the information obtained from the incorrectly called variants ( $h(S^F | S^G)$ ) and the information obtained from all the called variants ( $h(S^F)$ ),

namely

$$FDR(S^F(k)) = h(S^F(k) | S^G) / h(S^F(k)) \quad (4)$$

Figure 4a shows that the false discovery rate for Hi-C data is lower compared to WGS data at lower coverages. We attribute it to the deeper sequencing of the genomics regions in close spatial proximity. Hence, sampling more reads from those regions at low coverages is more likely compared to uniform sampling of reads from WGS. ChIP-Seq data has comparable false discovery rate to WGS and Hi-C data, ChIP-Seq targeting CTCF having the lowest FDR (Figure 4b). We further find that assays targeting transcriptome such as WES and RNA-Seq produce the noisiest genotypes among all the assays, only around 10% of the called variants being the correctly called variants (Figure 4c).

## 2.5 Linking attack scenario

Linking attacks aim at re-identification of an individual by cross-referencing datasets (Figure 5a). For example, in an hypothetical scenario, the attacker aims at querying an individual's HIV status from his/her phenotype data. This phenotype data is released with the individuals' genotype information with an anonymized identifier for each individual. We assume that adversary obtains access to this dataset either lawful or unlawful means. Now let's assume that attacker has access to a biosample. This could be partial or complete mapped reads from functional genomics experiments or a saliva sample taken from a used glass. The idea is to do genotyping to the biosample and find the matching genotype in the HIV status database. However, individuals share many common variants with each other. The number of shared variants between individuals is large within a racial population and even larger within a family. Then the question becomes how well an adversary has to sequence an individual's genome to be able to do successful linking. Specifically, adversary is interested in investigating whether noisy and partial reads from functional genomics experiments can be used as quasi-identifiers and how accurate the genotyping need to be

in order to link individuals to databases.

For this, the attacker calls variants directly from the reads of anonymized functional genomic experiments. Then he/she compares the called noisy and incomplete genotypes to the genotype data panel and finds the entry with the highest pointwise mutual information. This reveals the sensitive information for the linked individual to the attacker. We then consider a scenario that the attacker has access partial or increasing amount of reads to find out when the data crosses the set point and becomes private.

Based on the pmi values of each experiment at different coverages, we define a metric for linking accuracy called  $gap_i$ . To calculate this metric, we first rank all the  $pmi(S^F(k); S^i)$  where  $S^F(k)$  is the set of called genotypes from the functional genomics experiment at total coverage  $k$  and  $S^i$  is the set of genotypes of individual  $i$  in the panel of genotypes.  $gap_i$  for each individual  $i$  at total coverage  $k$  is calculated as;

$$gap_i = \begin{cases} \frac{pmi(S^F(k); S^i)}{pmi(S^F(k); S^j)}, & \text{if } rank(pmi(S^F(k); S^i)) \leq 5 \text{ and } rank(pmi(S^F(k); S^j)) = 2 \\ 0, & \text{otherwise} \end{cases}$$

We then define that if  $gap_i$  is 0 for the individual  $i$ , whose functional genomics data is used, then the individual cannot be identified as there are other individuals in the panel that have the matching genotypes. If  $0 < gap_i \leq 1$ , then the individual  $i$  might be vulnerable with auxiliary data such as gender or ethnicity, because he/she is in the top 5 matching individuals. If  $1 < gap_i \leq 2$ , then the individual  $i$  is vulnerable as we can identify him/her with 1 to 2 fold difference between him/her and the second best match. Lastly, if  $gap_i > 2$ , then the individual is extremely vulnerable with more than 2 fold difference between him/her and the second best match (Figure 5a).

We find that NA12878 is extremely vulnerable even at the lowest sampled coverages for Hi-C and RNA-Seq data (Figure 5b). More interestingly between around 1.1 and 10 billion basepairs, the Hi-C data exhibits higher linking accuracy than WGS data, consistent with the previous observation of pmi shown in Figure 3a. The total of coverage of ChIP-Seq data compared to Hi-C and RNA-Seq is quite low (SI Table I). However, the linking accuracy of ChIP-Seq is as good as Hi-C and WGS (Figure 5b), which shows extreme vulnerability of individuals with respect to release of such small amount of data. More strikingly, attacker can link NA12878 by using the reads of single-cell RNA-Seq data, which cover a small portion of the genome in a single cell (Figure 5d). We then added the variants of NA12878’s parents to the 1000 genomes genotype panel and repeated the linking attack. We found that although NA12878 is still extremely vulnerable to re-identification in the presence of her parents in the database, the second best matching individuals are her parents (SI Figure 2). This shows that using the metric *gap*, an adversary can also identify individuals related to the target individual.

## **2.6 Individual’s genome can be accurately approximated from publicly available data by imputation**

To answer the question whether an attacker can correctly assemble an individual’s variants by only using the reads from ChIP-Seq and RNA-Seq experiments, we impute variants by using IMPUTE2 [29, 30, 31] and the variants called from ChIP-Seq and RNA-Seq experiments. We then collected all the called and imputed variants in a set. Although imputed variants do not contribute to the information due to high correlation with the called variants (SI Methods and SI Figure 3), total number of captured variants increases significantly (Figure 6a). By using shallow sequencing data of ChIP-Seq and RNA-Seq, we were able to call and impute variants almost as many as the gold standard variants.

We then ask the question if we can infer potentially sensitive phenotypes from these variants. Figure 6b shows a small set of example variants associated with physical traits such as eye color, hair color or freckles. Many of these variants are in the called set of Hi-C, ChIP-Seq and RNA-Seq data. Number of variants associated with traits further increases with imputation as expected.

## 2.7 Toy model for estimation of amount of leaked data without variant calling

Genotyping from DNA sequences is the process of comparing the DNA sequence of an individual to that of reference human genome. To be able to do successful genotyping, one needs substantial depth of sequencing reads for each base pair. According to the Lander-Waterman statistics for DNA sequencing, when random chunks of DNA is sequenced repeatedly, the depth per basepair follows Poisson distribution with a mean that can be estimated from the read length, number of reads and the length of the genome [32]. Since functional genomics experiments aim at finding highly expressed genes, TF binding enrichment or 3D interactions of the genome, it is expected that the sequencing depth per basepair does not follow the Poisson statistics. Thus, the genotyping using reads from functional genomics experiments is biased towards the variants that are in the functional regions of the cell types/lines of interest.

To this end, we hypothesized that the genotyping from the sequencing based functional genomics data depends on the average depth per base pair ( $\bar{d}$ ), the total fraction of the genome that is represented at least by one read, also called the breadth ( $b = \sum_{i=1}^N [d_i \geq 1]$ ,  $N$  is the total number of nucleotides in the genome) and a parameter  $\beta$  that estimates the sequencing bias, i.e. how much the distribution of depth per basepair deviates from the Poisson distribution (Fig. 6c). The bias parameter  $\beta$  is composed of two terms: (1) the negative bias  $\beta-$  and (2) the positive bias  $\beta+$ . Negative bias estimates if there is an increase in the number of low depth basepairs relative to mean with respect to expected Poisson distribution and the positive bias estimates the increase in

the number of high depth basepairs (see SI for more details).

$$\bar{d} = \frac{\sum_{i=1}^N d_i}{N}$$

To quantify the genotyping from the functional genomics data, we used “naive” normalized pointwise mutual information (npmi). It takes into account the information from the correctly identified genotypes ( $pmi(S^F; S^G)$ ), the information missed that is in the gold standard ( $h(S^G | S^F)$ ) and the information from the incorrectly identified genotypes, i.e FDR ( $h(S^F | S^G)$ ) as;

$$npmi(S^F; S^G) = \frac{pmi(S^F; S^G)}{h(S^F, S^G)} = \frac{pmi(S^F; S^G)}{h(S^G | S^F) + pmi(S^F; S^G) + h(S^F | S^G)} \quad (5)$$

With the assumption of  $npmi(S^F; S^G) = f(\bar{d}_F, b_F, \beta_F)$ , we used Gaussian Process Regression (GPR) [?] to fit 40 training data points and achieved a root mean square error (RMSE) of 0.06 with the values ranging between [0,35] (Fig. 6d). 5 separate data points were used as test set and an RMSE of 0.07 was achieved (Fig. 6d), see SI for more details). The regression learning is performed using 10 fold cross-validation to protect against overfitting. This toy model represents a proof of concept suggesting a theoretical framework for the estimation of amount of leaked data from functional genomics experiments without the need of performing time-consuming genotyping calculations.

## 2.8 Unique combination of common variants contribute significantly to the information leakage and linking accuracy

We next analyze whether a linking attack can be prevented by removing rare variants from the datasets as their contribution to the information is the highest. We first speculated that the removal of the variants that are unique to NA12878 might be enough to fail at linking. A total of 11,472 variants along with their genotypes are only observed in NA12878, which we refer as ‘unique variants’ (Fig. 6a). **After the removal of unique variants** from the NA12878 variant set,

we calculated the  $gap_{NA12878}$  and surprisingly found that linking accuracy is affected minimally compared to using the all of NA12878 variants (Fig. 6b). We then created another set (‘double variants’, Fig. 6a), that includes the variants that are observed in NA12878’s genome as well as one more individual in the 1000 genomes genotype panel (total of 16,305 genotypes). We again found that individual is extremely vulnerable to linking attacks ( $gap_{NA12878} > 2$ , Fig. 6b). We then relaxed our cut-off further to remove the variants that are observed in NA12878’s genome as well as at most 1.5% of the population (‘rare variants’, total of 124,093 genotypes, Fig. 6a). This also did not affect the overall linking ( $gap_{NA12878} > 2$ , Fig. 6b).

These rare genotypes are observed in 64 or less individuals including NA12878. A practical solution to the re-identification problem using functional genomics data would be masking or removing such rare genotypes from the reads. However, as iteratively shown here that although rare variants are extremely informative and sufficient enough to do re-identification through linking attacks, their removal is not sufficient to fail at re-identification. That is, not only the rare genotypes but also the unique combination of common genotypes are identifiers of genetic make-up of an individual. To further support this calculation, we added the genotypes of the parents of NA12878 to the panel and found that we can still link NA12878 to the correct genotypes successfully with an extreme vulnerability ( $gap_{NA12878} > 2$ , SI Fig.2).

We then analyze the contribution of small indels to the naive information and whether accurate linking is possible when we remove all the single nucleotide mutations from the data and keep the indels. Fig. 6c shows the information contribution of the indels. Although naive pointwise mutual information from indels are much smaller compared to single nucleotide mutations, a high linking accuracy can be achieved by using only indels even at small coverages (Fig. 6d). This linking attack is done using the most noisy data set we have (total RNA-Seq) to make linking more difficult.

## 2.9 Privacy-preserving file formats for alignments from functional genomics experiments and their relation to differential privacy

After discovering neither common variants nor indels can be publicly shared, we seek for ways to share the mapped reads of functional genomics data. The purpose is to share maximum amount of information with minimum utility lost while maintaining the individual's privacy. As a privacy metric, we aim to prevent leakage of any variants as well as any quasi-identifier that can lead to identification of position of variants in the genome. For the utility measures, we borrowed concepts from differential privacy and introduced a user identified privacy-utility balance that can be adjusted according to the patient consents and policies.

Differential privacy ensures a high level of privacy such that adversary retrieves similar result with and without the addition of the individual's data to the database [?]. An algorithm  $A$  that retrieves results  $A(D)$  from database  $D$  is considered  $\epsilon$ -differentially private if the results satisfies the condition

$$\frac{\text{prob}(A(D) = C)}{\text{prob}(A(D_{\pm i}) = C)} = \exp^{\epsilon}, \quad (6)$$

where  $D_{\pm i}$  indicates the addition or subtraction of  $i^{\text{th}}$  individual to the database.

Although, differentially private solutions by definition are applied to the databases of individuals, a similar logic can be applied to raw sequence alignment data from functional genomics experiments. Our hypothesis is that since gene quantification or TF binding peak calling do not necessarily depend on the individual's genotype, masking or removal  $q$  amount of variants from the alignment files minimally (on the level of  $\epsilon$ ) affect the functional genome quantification. That is, we assume a BAM file of a functional genomics experiment is the dataset  $D$ , where each record is a string with the information of number of matched, mismatched, inserted or deleted basepairs in a read (also known as a cigar). If we create a new file format (called pBAM) that is referred as  $D_{\pm q}$

where we change  $q$  number of records such that cigars no longer carry any labels corresponding mismatches, insertions or deletions. If we calculate depth signal for each genomic location  $i$  in  $D$  and  $D_{-q}$ , then we obtain

$$\frac{\text{prob}(f(D) = C)}{\text{prob}(f(D_{-q}) = C)} = e^{\varepsilon_i}, \quad (7)$$

which can be rewritten as

$$\varepsilon_i = \ln \text{prob}(f(D) == C) - \ln \text{prob}(f(D_{-q}) == C) \quad (8)$$

In equation 8  $f(D)$  is the function that computes the depth of a genomic location  $i$  from the BAM/pBAM file  $D/D_{-q}$ . Since depth of a genomic location  $i$  is not informative without the depth of the rest of the genome, we used z-scores of the depth for  $\text{prob}(f(D) == C)$ , as

$$\varepsilon_i = \ln\left(\frac{d_i - \bar{d}}{\sigma(D)}\right) - \ln\left(\frac{d_{i-q} - \bar{d}_{-q}}{\sigma(D_{-q})}\right) \quad (9)$$

We then calculated the  $\varepsilon^q$  for the new file format as  $\varepsilon = \max_{i \in (1, \dots, N)} \varepsilon_i^q$ . As the  $\varepsilon$  is a privacy measure, we used  $U^q = \frac{1}{\varepsilon^q}$  as the utility measure of the new file format. As the purpose of functional genomics experiments is to annotate functional genome, the utility metric measures the quality of the annotation when the analysis tools are performed using privatized file formats, which could be signal depth profile in basepair and exon resolutions or gene quantifications.

The privatized file format pBAM is constructed as following. The reads from the BAM files are categorized as perfectly mapped reads that includes also intronic reads and reads with mismatches, insertions, deletions, soft- and hard-clipping. We remove the sequence of the reads and keep mapping quality, start coordinates, fragment lengths and flags related to mappability of the reads while adjusting the cigar and alignment scores such that leakage of variants are masked (Fig. 8). The details of how new file format deals with reads are reported in detail in SI Methods with a detailed

figure (SI Fig. 3). We also created pBAM files for the BAM files that are obtained by aligning threads to transcriptome which is necessary for gene quantification (in SI Methods).

Such treatment of reads introduce noise to the signal profiles especially with deletions since the start coordinates and total length of the fragments are unchanged (Fig. 8a-b, see SI Methods and SI Figure 4). However, our utility analysis showed even when  $q$  is the all SNVs in the BAM files,  $x\%$  accordance with the original depth of the nucleotides,  $y\%$  accordance with the original depth averaged over exons and 100% recovery for gene quantifications. [[GG: will be updated as:As can be seen from the scatter plots, noise is mostly introduced to basepairs with low depth (Fig. 8c-d).]] The pBAM file format contains the necessary information to be used in functional genomics pipelines such as gene expression quantification and transcription factor binding peak calling. We then create a “.diff” file that contains the information that are distorted in the pBAM files, except the sequence of the reads. Instead of reporting the entire sequence of a fragment, we reported the nucleotides that are different than the reference sequence (see SI). “.diff” files are private files that require special permission for access. The advantage of locking up the “.diff” files instead of the entire BAM files is that they are smaller in size, hence it is easier to store and move these files. A user is able to reach the original BAM file when they have access to the .diff file and our collection of scripts called ptools can convert pBAM + .diff + reference genome into the original BAM file (Fig 8b).

### 3 Discussion

Functional genomics experiments provide large amount of biological data. These are large-scale, high-throughput assays based on sequencing. Although they aim at answering questions related to genomic activities such as gene expression, TF binding or 3D organization of genome, public sharing of sequencing data from these experiment can lead to recovery of genotype information

and in turn raise privacy concerns. However, the systematic quantification of private information content of the functional genomics BAM files and open access to such data without compromising individuals' identity have not been well studied. Current policies regarding to public sharing of functional genomics BAM files are ad-hoc. The experiments that require high depth of sequencing such as Hi-C and sometimes RNA-Seq are considered to be private, while relatively low depth BAM files such as those from ChIP-Seq are often shared publicly. In this study, we derived information theory based measures to systematically quantify the sensitive information leakage in the BAM files of functional genomics experiments in low and high depth experiments.

Instantiation of linking attacks by genotyping of partial or complete functional genomics data showed that even at low coverages of low depth experiments such as ChIP-Seq, linking individuals to the databases can be done without error. When we compare the linking accuracy to the false discovery rate, we found that it is easier to link individuals to the databases than genotyping them accurately using functional genomics experiments. The implication is that noisy quasi-identifiers, i.e bad quality SNP calling, can be used to link the data to the high quality genotypes. For example, according to our calculations, reads from single-cell RNA-Seq data carry the most amount of noise. This is likely due to the bias towards expressed genes in such small amount of cells, mapping issues of splice sites, false positives from RNA editing sites and amplification bias. However, the noisy genotypes called from small amount of cells, even when the number of reads are only a million, are quasi-identifiers that result in very high linking accuracy. This is worrisome in terms of biomedical data sharing as the number of individuals in genotype databases is increasing exponentially with the decreasing cost of sequencing. Furthermore, rich information about an individual's identity and his/her sensitive phenotypes can also be inferred by combining the reads from low depth functional genomics experiments and through genotype imputation.

In this study, we also discuss the concept of “set point” in determining the data production steps, where sensitive information leakage and utility of the data are balanced (Fig. 1). Setting a “set point” is possible by systematic genotyping and quantification of information. Although it is obvious that any DNA read contains variants, it is not trivial to understand the amount and the quality of sequencing to do accurate genotyping. Moreover, we showed that genotyping accuracy of a functional genomics sample and the ability to link individuals to the databases using the same sample are not necessarily linearly correlated. It is easier to link individuals to the databases and infer their complete variant sets than genotyping a sample with accuracy and minimal false discovery. For example, complete set of variants from HeLa’s genome may not be obtained by genotyping HeLa BAM files from functional genomic experiments. However, using only a small number of reads from the same BAM files accurate linking attacks are plausible. That is, noisy and incomplete genotyping from partial sequencing experiments can serve as strong quasi-identifiers, which is not straightforward to predict at first. Nevertheless, policies governing public sharing of HeLa genome vs. HeLa functional genomics reads is ad-hoc and contradictory. Therefore, it is essential to quantify the information in samples and set the “set point” accurately. On the other hand, functional genomics experiments advanced our understanding of health and disease by revealing function of the genome under different conditions. The quantification, analysis and the interpretation of functional genomics data are still an evolving field, hence extensive public sharing of functional genomics data accelerate collaborative research and reproducibility by removing the complexities associated with data accession procedures.

The increasing incentive to share data for the advancement of biomedical research and the correlated increasing privacy concerns have led researchers to look for more complex solutions to overcome the bottleneck between data-sharing and privacy preserving means. Solutions such as differential privacy has been proposed [?, ?, ?]. It has shown that retrieving summary information from private statistical databases without revealing some amount of individuals’ information is

impossible [?]. Furthermore, entire database can be inferred by using a small number of queries. Differential privacy ensures a high level of privacy such that adversary retrieves similar result with and without the addition of the individual's data to the database [?]. Although such concept might be useful for sharing summary statistics of functional genomics data from multiple individuals, it is conceptually hard to envision the applications to the raw mapped read sharing from functional genomics experiments taken from a single individual. By borrowinf language from the concept of differential privacy, we created privacy-preserving binary allignment files (pBAM) to enable public sharing of raw data. We developed a framework, where researchers can tune the level of privacy and utility balance they want to achieve based on the policies and consents of the donors.

pBAMs enable researchers to share the mapped reads, which are largest data product of functional genomics experiments. To easen the challenges associated with moving and storing of large special access files, we created light-weight .diff file format that consists of the differences between pBAM and BAM files in a compact format. This allows us not to repeat the sequence information in the human reference genome files in .diff files and reduces the size of the private files significantly. Our file formatting system is currently adopted by ENCODE Data Coordination Center for sharing raw reads of experiments from individuals, who do not consent public sharing of their genotype data. Presented framework can be used for quantification of sensitive information from the raw reads of functional genomics experiments and conversion of raw files to privacy-preserving file formats. We address the most obvious leakage and provide solutions for quick quantification and safe data sharing. However, it is useful to review all the sources of information leakage from functional genomics experiments. For example, the next source of leakage is from the signal profiles in RNA-Seq, which was addressed elsewhere [18]. There is also leakage from gene expression quantifications, which was shown to be connected with variants through the eQTLs [17]. We also anticipate more leakages to be discovered as new functional genomics experiments are developed. Combined with the increasing attention to genomic privacy, we expect future studies will lead to

novel privacy-preserving solutions in an open data sharing mode.

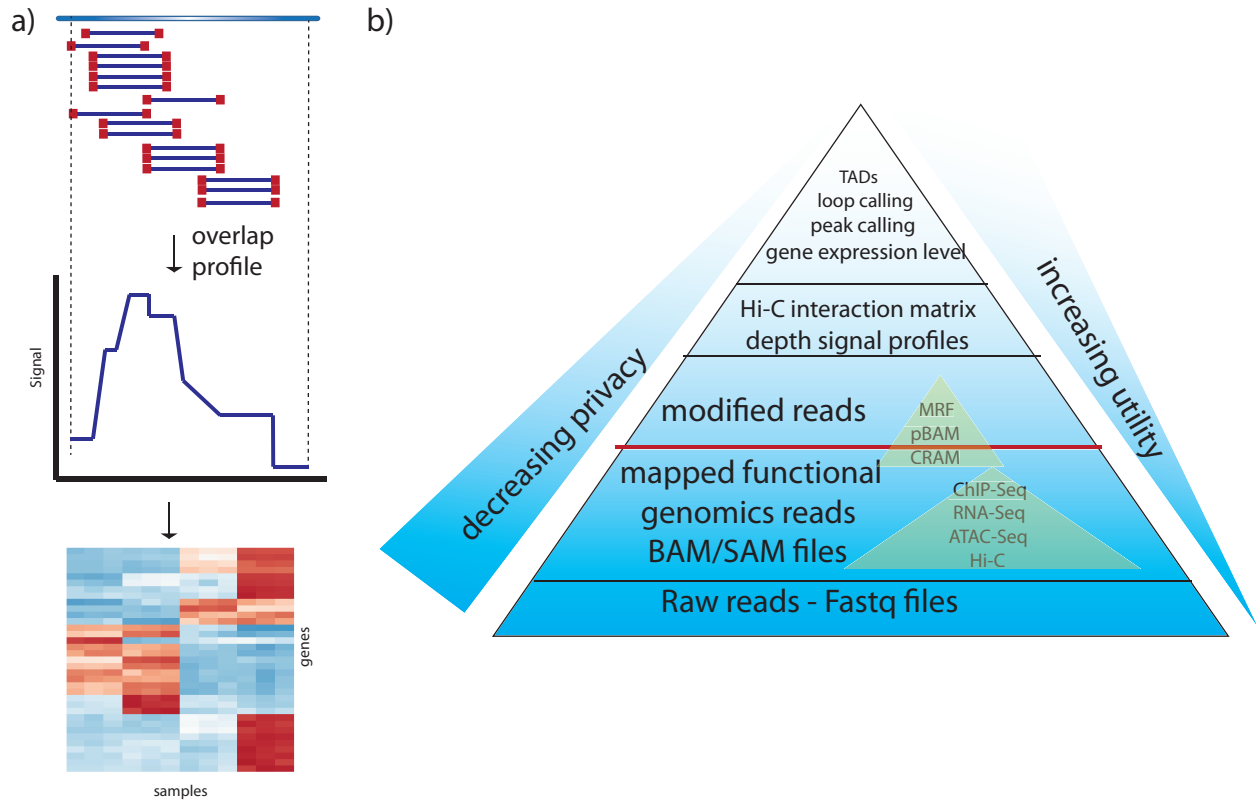

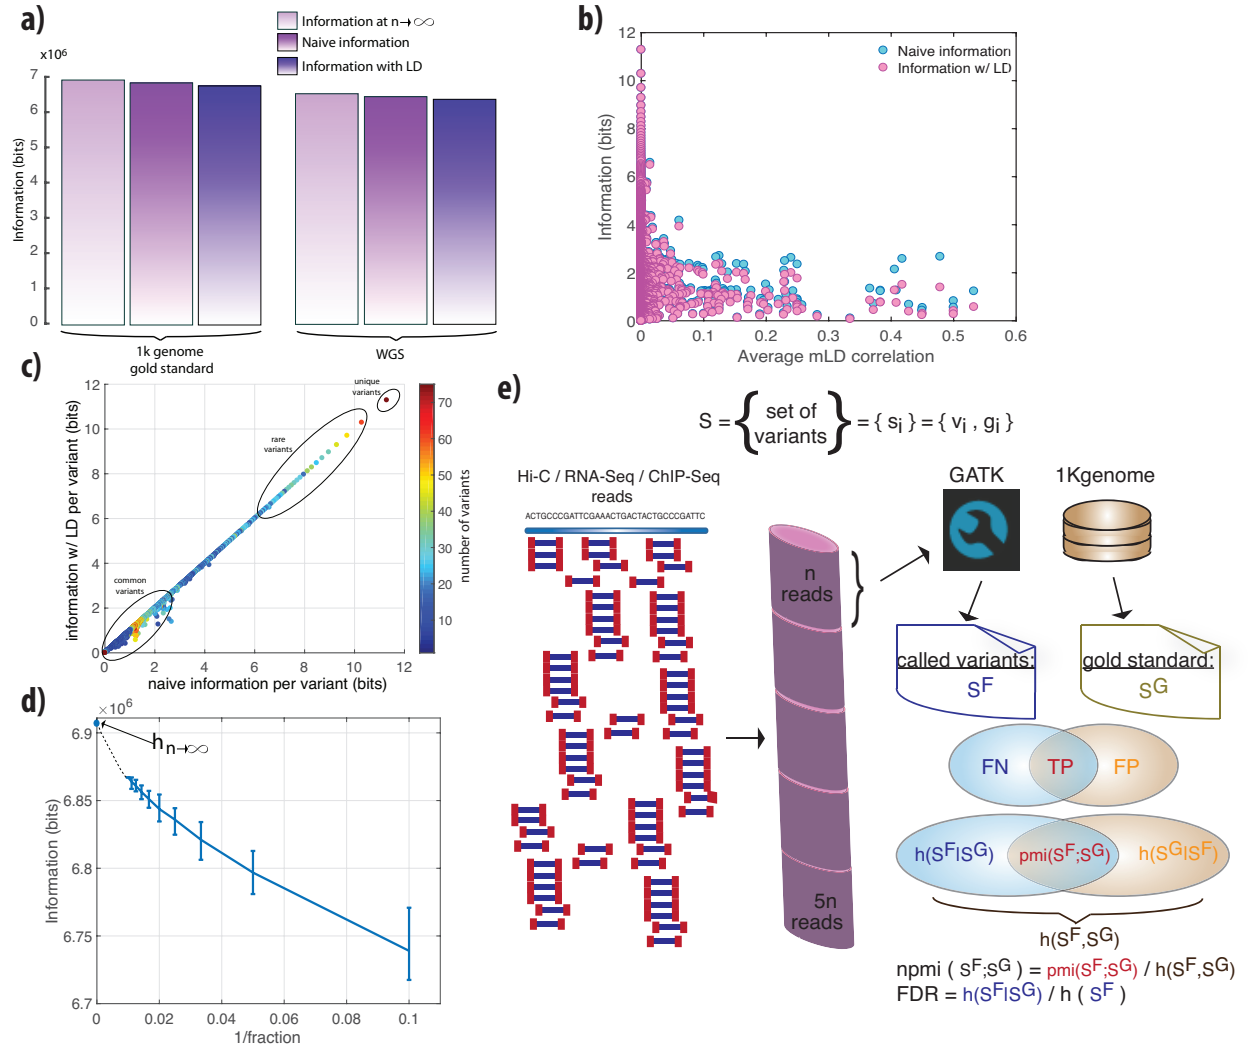

Figure 1: **Schematic of data types from functional genomics experiments.** (a) The flow for RNA-Seq data processing from mapped reads to the gene quantifications. (b) Different layers of produced data from RNA-Seq pipeline. Red line denotes the set point, where privacy and utility trade-off balanced.

**Figure 2: Comparison of naive information measure with information with LD consideration and sample size correction.** (a) Difference between the naive information, information with LD consideration and extrapolated information when population size is infinite. (b) The maximum LD score for each variant are averaged over per information and plotted against information. Highly informative variants do not exhibit difference when information is calculated using naive approach vs. with LD consideration. (c) Naive information vs. information with LD consideration per each variant in an LD block. Only low information variants show slight difference between two approaches. (d) Naive information vs. inverse fraction of the data sampled from the 1000 genomes population. y-intercept is extrapolated from the fitted curve and denotes the information when the population size is infinite. Error bars are calculated using  $100\times$  bootstrapping. (e) The process of sampling reads from functional genomics experiments for the calculation of pointwise mutual information between 1000 genomes gold standard variants for NA12878 in different coverages.

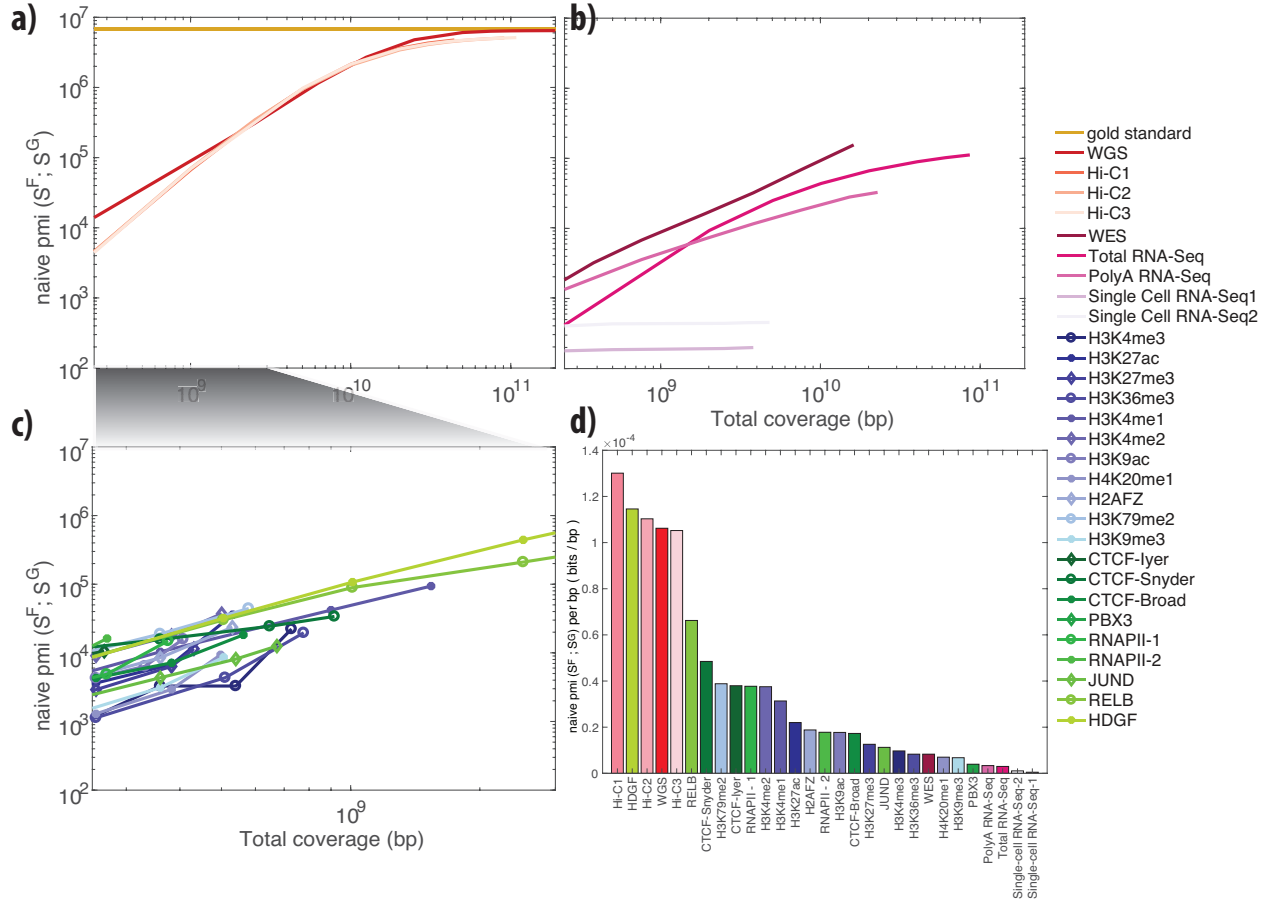

Figure 3: **The pointwise mutual information calculated for 24 different functional genomics assays and WGS, WES and SNP ChIP data using NA12878 1000 genomes variants as gold standard.** (a) The pmi values for WGS and three different primary Hi-C experiments plotted at different coverages. The information contents of the gold standard (1kG in blue) and SNP ChIP (in pink) are added for comparison. (b) The pmi values for 20 different ChIP-Seq experiments targeting histone modifications and transcription factor binding plotted at different coverages. (c) The pmi values for WES, total RNA-Seq, polyA RNA-Seq and single-cell RNA-Seq from two different cells plotted at different coverages. (d) The pmi values per basepair plotted using the mean of all the ratios between the pmi and the corresponding coverage.

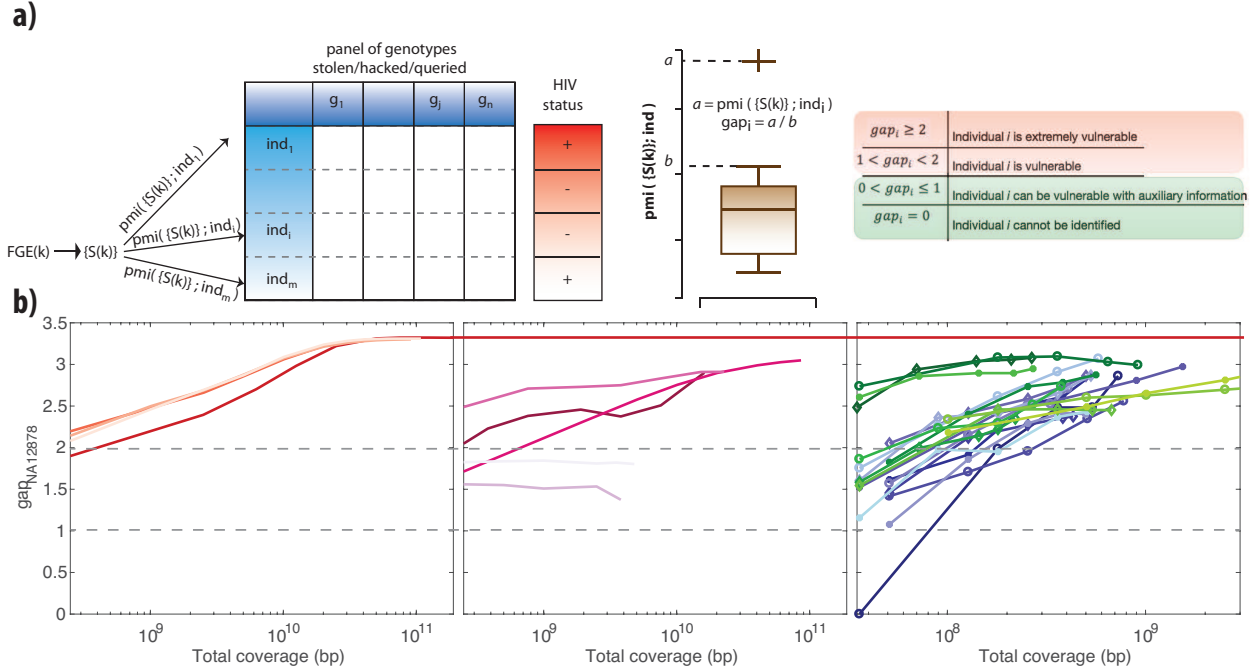

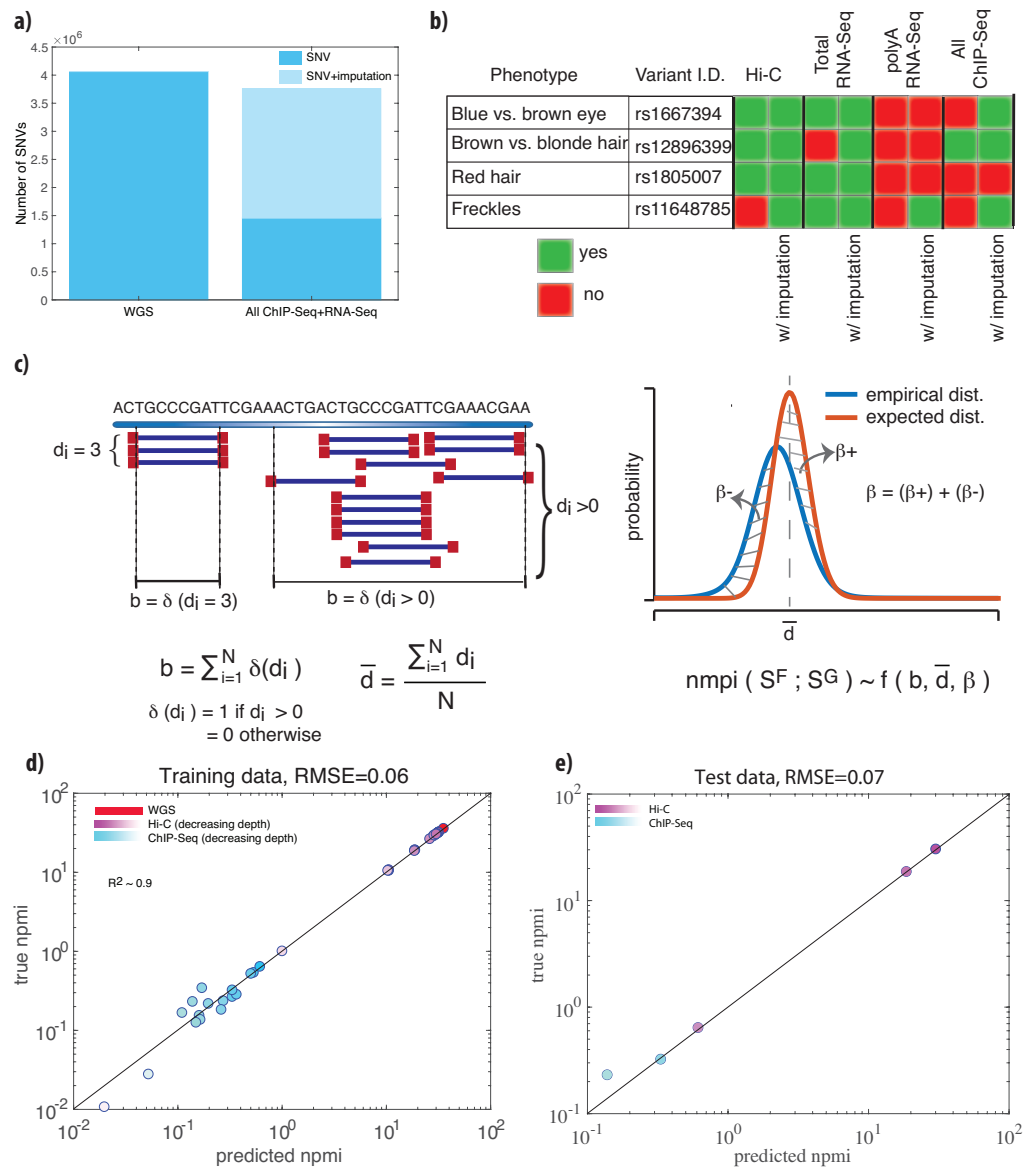

Figure 4: **False discovery rate of functional genomics experiments at different coverages (a)** FDR comparison for Hi-C and WGS data at different sampled coverages. **(b)** FDR comparison for different ChIP-Seq experiments at different coverages. **(c)** FDR comparison for WES and different RNA-Seq experiments.

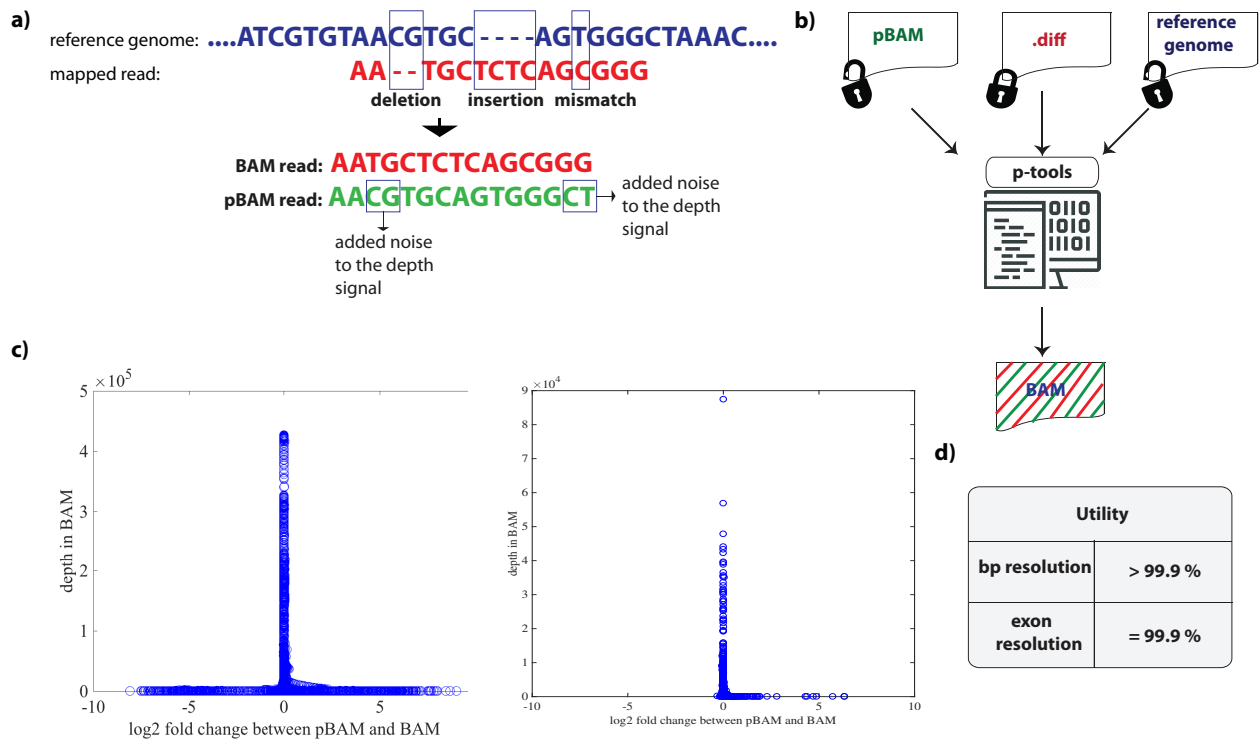

**Figure 5: Illustration of a linking attack and the accuracy of linking.** (a) The publicly available anonymized reads from functional genomics experiments contains a set of variants and HIV status for the sample that the functional genomics experiment was performed at increasing coverages. The panel of genotypes contains the variants and associated genotypes for  $m$  individuals. The attacker links the inferred variants and genotypes to the panel of genotypes by using the best matched pointwise mutual information. The linking potentially reveals the HIV status for the linked individual. (b) Comparison of  $gap$  for NA12878 at different coverages for Hi-C and Total/PolyA RNA-Seq reads. WGS and SNP-ChIP are also added for comparison. (c) Comparison of  $gap$  for NA12878 at different coverages for 20 different ChIP-Seq experiments. (d) Comparison of  $gap$  for NA12878 at different coverages for single-cell RNA-Seq experiments.

**Figure 6: Individual’s genome can be approximated and sensitive phenotypes can be inferred from publicly available data by imputation and a theoretical framework for prediction of amount of leaked data (a) Number SNVs called from WGS data and all of the ChIP-Seq and RNA-Seq data together with and without imputation. (b) Variants associated with physical traits and if they present in the called variants from different functional genomics experiments before and after imputation. (c) Features of the theoretical framework - write more. (d) Accuracy of fitted model on training set- write more (e) Accuracy of fitted model on test set - write more**

**Figure 7: Removal of rare variants and linking** (a) Information of the variant before and after addition of NA12878 to the population. We iteratively removed variants from the set as (I) only the variants that is only NA12878 specific, (II) the variants that have an information of 11 or higher bits after removal of NA12878 from the population, (III) the variants that have an information of 6 or higher bits after removal of NA12878 (b) Linking accuracy for every iteration of removal of NA12878 variants from the set. (c) Information of all the variants that are called from Total RNA-Seq reads vs. the information of the indels that are called from Total RNA-Seq reads. (d) Linking accuracy when we consider all the variants that are called from Total RNA-Seq reads vs. the linking accuracy when we consider only indels called from Total RNA-Seq reads.

**Figure 8: Privacy-preserving file formats for mapped reads** (a) The generation of public pSAM and private .diff files. (b) Schematic of how to go between pBAM and BAM formats by utilizing the human reference (c) Comparison of number of reads for each basepair in the original SAM file and the distorted pSAM file. Noise is mostly introduced to basepairs with low depth. (d) Comparison of number of reads for each exon in the original SAM file and the distorted pSAM file. Noise is mostly introduced to exons with low expression.
