-- Ref1.1.1 - Presentation of in vivo validations --

<ASSIGN>MTG

<PLAN><u>need to incorporate text into draft</u> <STATUS>80%

Deleted: Agree and Fix

Reviewer Comment	I understand that the authors tested 102 predicted mouse enhancers (plus 31 human orthologs) in transgenic mice, and had another 151 regions from an independent unpublished effort (Moore, in review) available for comparison. This is an unprecedented effort to assess enhancer predictions in vivo, making a systematic and rigorous comparison between the predictions and the experimental outcomes of the in vivo assays highly interesting. However, I find the presentation in the main text and figures not satisfying and partly confusing. For example, what does "61% predicted active rate versus 70% observed active rate" (page 10) mean? I interpret this statement as 61% of the tested regions were predicted to be positive and 70% of the tested regions were found to be positive - there is no indication if the predicted and observed positives actually agree.
Author Response	Thanks the reviewer for pointing this out. We agree that this sentence is a bit confusing and we'll rewrite it. Here we are describing the experimental test result of 62 elements chosen from top, middle and bottom rank of forebrain H3K27ac signal (e.g. how many of them are active in each tier). We made a rough estimation of whether these elements would be active by their overlap with the DHS peaks, but since this estimation is not very relevant, we can remove it to avoid confusion. A rigorous assessment of <u>the</u> our model prediction using these experimental data is presented later in the table and ROC/PR curve of Figure 4. Here we are showing that indeed the highest ranking tier has the highest validation rate, and we provide the detail validation result of each element in the supplementary table.

Reviewer Comment	It is my understanding that the authors have predictions for different mouse tissues and - for each tested candidate - have a readout of activity across the entire embryo, i.e. all tissues. This should allow the rigorous assessment of the prediction accuracy per tissue in comparison to an appropriate random model that accounts for the overall number of active regions per tissue (I assume Fig. 4B and C come close to this, but the corresponding text is confusing - I don't understand what Fig. 4A corresponds to).		
Author Response	Thanks to the referee's comment. We have revised the manuscript and Figure 4 to clarify and incorporate the referee's points. In addition, since ENCODE has updated its ChIP-seq processing pipeline and reprocessed many of the ChIP-seq data, we redid our evaluation on mouse with the newly processed data and updated the figures accordingly. Please refer to the excerpt below	-	Deleted: Indeed each candidate has a readout for all tissues in the embryos. Figure 4B and 4C use this experiment read out to evaluate the prediction. The ROC curve evaluates the false positive rate and true positive rate of our prediction in each tissue at different threshold, and the PR curve evaluates the precision and recall of the prediction. At random, the ROC curve is a diagonal line with AUROC of 0.5, and PR curve is a horizontal line with AUPR equal to the fraction of positives. In 4A the table contains the average ROC/PR of the evaluation results from six different
Excerpt From Revised Manuscript	To test the activity of predicted mouse enhancers in vivo, we performed transgenic mouse enhancer assay in e11.5 mice for 133 regions in heart and forebrain, including 102 regions selected based on the H3K27ac signals rank of corresponding mouse tissues, and 31 regions selected by an ensemble approach from human homolog sequences. For each tested candidate, a read out of activity across the entire embryo is collected. The number of transgenic mice that showed the pattern for each tissue is also recorded for reproducibility check (See Methods and Supplement Table S4, S5). In addition, we obtained another set of transgenic mouse enhancer assay results from ENCODE Phase III Encyclopedia (Moore et al., in review), which assessed 151 regions in mouse e11.5 hindbrain, midbrain and limb. The combined results from these two large sets of validations, as well as any previously tested tissue-specific e11.5 enhancers from VISTA database, allow us to comprehensively evaluate our enhancer predictions in all six e11.5 mouse tissues.		ROUPER of the evaluation results from six different tissues. We are reporting averaged numbers. We have modified the text to make this clearer. [1] Formatted: Font:Arial, 7.5 pt, Bold [1] Formatted: Left, Line spacing: multiple 1.15 li, Border:Top: (No border), Bottom: (No border), Left: (No border), Right: (No border), Between : (No border)
	We evaluated the predictability of our matched filter model for each individual histone marks and DHS, as well as the integrated SVM model (Figure 4). For each tissue, our model ranks all the tested candidate elements with their predicted activity in this tissue using either individual feature or the integrated SVM model. Then the label of each element from experiment read out is used to assess the predictions with ROC and PR curve. One average, the integrated model trained with drosophila STARR-seq data achieves an AUROC of 0.80 and an AUPR of 0.37 for tissue- specific enhancer predictions in mouse (Figure 4A). Unlike AUROC, where the baseline is always 0.50, AUPR is more		Formatted: Font:10 pt, Not Highlight Formatted: Not Highlight

sensitive to the positive to negative ratio, with a baseline being just the positive rate. Since the positive rate from the experiment varies from 8.8% 17.6% among the tissues, the AUPR has a larger variance compared the AUROC.

NG Consistent with previous findings from STARR-seq data, when we assess each histone modification signals independently in mice,

H3K27ac signal remains best performed histone marks for predicting enhancers, In addition, the DHS signal also performs well as an independent source, as it likely shares some common information with H3K27ac., The integrated model performs similar with the highest prediction feature in each tissue. This is likely due to the fact that the model is trained entirely with drosophila matched filter scores and might not be best optimized in the mammalian systems. We believe that the integrated model would achive better performance when applying our framework directly to mouse tissue STARR-seq dataset when it becomes available.

We also did similar evaluation using the regulatory elements identified by the transduction-based FIREWACh assay in mouse embryonic stem cells (mESC) [36]. With the same metaprofiles, the predictions are based on epigenetic signals of mESC available from ENCODE website Again, we observe similar results for individual histone marks and combined SVM model (Figure S16). As the in vivo and FIREWACh assays utilized a single core promoter to validate regulatory regions, the performance of the different models in Figures 4 and S16 are probably underestimated.

Reviewer Comment	Figure 5 shows an IRES-GFP construct, which is typically used in combination with a selection marker, yet no such marker is shown and the methods don't indicate selection (which would distort enhancer activity measurements).
Author Response	IRES-eGFP was used downstream of the DNA elements to allow flow cytometric analysis of positive cells after cell transduction. The presence of a selectable marker gene would have needlessly increased the size of the vector, which would be problematic for some of the longer elements. IRES was used so that there would be eGFP translation/readout even if transcription began within the element itself, several kilobases upstream of eGFP start codon.

<ASSIGN> MTG

<PLAN> recalculation/Exclude midbrain

<STATUS> 50%

Reviewer	The authors compare their approach to chromHMM and SegWay,
Comment	which are both not built for enhancer prediction but rather
	to segment the genome into different types of regions. A
	more relevant comparison to a supervised machine learning
	approach (Capra, ref 64) is presented only superficially in
	the methods section and without any (supplementary) figure.

Author Response	With the referee's suggestion, we did more comparison with other published methods, and we have included the results in our manuscript as shown below. In our original submitted manuscript, we compared our method with ChromHMM and SegWay because the ChromHMM and SegWay enhancer annotations of the Roadmap Epigenetics samples has been used in many publications to define enhancer		Formatted: Border:Top: (No border), Bottom: (No border), Left: (No border), Right: (No border), Between : (No border) Deleted: they were built for segmentation of the genome and provided annotations for different genomic regions. The
	regions. We want to compare with them to show that our framework provides a better set of enhancers readily available for related studies.		
Excerpt From Revised Manuscript	In addition to the comparison with unsupervised segmentation based methods, we also compared with other published enhancer prediction tools, including CSIANN, a neural network based approach; DELTA, an ensemble model integrating different histone modifications; RFECS, a random forest model based on histone modifications, and REPTILE, a more recent published method that integrates histone modifications and whole genome	-	Formatted: Left
	bisulfite sequencing data. We used their published results and compared their methods with our model on the same experimental data reported in their paper(\cite()). The comparison was done in a tissue specific manner for all four mouse tissues with all required ChIP-seq and DNase experiment data available. For 3 out of 4 tissues in the comparison, our prediction shows higher AUROC than the other four published methods. In midbrain, the AUROC for our prediction is slightly lower than REPTILE and RFECS, possibly due to the data quality of the		Deleted: We show that our method also outperforms these previous approaches assessed by in vivo transgenic experiments.
	DNase experiment performed in midbrain. The DNase experiment of meuse E11.5 stage midbrain is marked as low spot score in ENCODE. We found that while 75% to 81% of the genome regions has DNase signals in the other three tissues, only 52% of the genome regions show DNase signal in the experiment in midbrain. It is also worth noticing that our model is trained using the drosophila STARR-seq data whereas the other methods were trained directly with mouse data. We believe that our method would have better performance if mouse STARR-seq data could be applied for training in our framework.		2

-- Ref2.1a - Comparison with FANTOM5 and ENCODE --

STATUS>80%			ciciu.
Reviewer Comment	Page 3: "In addition to the small numbers, the validated enhancers were typically selected based on conserved noncoding regions [17] with particular patterns of chromatin [18], transcription-factor binding, [19] or noncoding transcription [20]."	F	ormatted Table
	Since the FANTOM5 Atlas is the most comprehensive collection of transcribed enhancers across different primary cells and tissues, I would like to see a comparison of the model predictions in human to the enhancer dataset of the FANTOM5 Atlas dataset taking into account cell-type/tissue specificity. In a similar fashion, what is the overlap with the integrative ENCODE annotation proposed by Hoffman et al. NAR 2013.		
Author Response	Thanks to the referee for this point. The FANTOM5 Atlas contains a good set of transcribed enhancers, although there is only a relatively small number of transcribed enhancers detected in each cell. Based on the referee's suggestion, we've checked our predictions against the FANTOM5 enhancer set and compared our overlap with the annotation provided by Hoffman et al, NAR 2013. We included the result in the supplement as reproduced below:		
Excerpt From Revised Manuscript (in suppl.)?	For predictions in human we compared with the integrative annotation of ChromHMM and Segway using CAGE-defined enhancers from FANTOM5 Atlas. We checked the overlap between our predictions with the FANTOM5 enhancers and		

compared that of the integrative annotation provided by Hoffman et al, NAR 2013 in a cell-type specific manner. The FANTOM5 Atlas has included three human cell lines from ENCODE project with enhancer predictions from both methods: GM12878, K562 and HepG2. We found that the percentage of overlap for our predicted enhancers is more than three times higher than that of the combined ChromHMM and Segway enhancers in each of these cell lines. Despite the fact that our framework predicted a smaller number of enhancers, the exact number of overlap is still higher for our predictions. Around 40% of the CAGE-defined enhancers overlap with our predicted enhancers, while 23% to 34% overlap with the enhancers predicted by integrative ENCODE annotation method.

predicted enhancers are shown in the bar plots. The left panel bar plot shows the fraction of overlap, over the total number of enhancers predicted in each method. The right panel shows the fraction of overlap over the total number of FANTOM5 enhancers.

<ASSIGN> MTG

<PLAN>Refer to 2.3 saturation analysis <STATUS>80%

Reviewer Comment	Another more technical comment is about usage of 10-fold cross validation. If the number of training and testing sample is large enough 10-fold cross validation is not necessary. 5-fold cross validation is sufficient or even 2- fold cross validation assuming big numbers of training and testing data (e.g., more than few thousands).
Author Response	We thank the referee for the comment. We agree to the referee that the 5-fold or even 2-fold cross validation might be sufficient. This can be viewed from the saturation analysis under the above section 2.3. We added this point in the supplement shown below.
Excerpt From	The result shows that the average AUPR increases with increasing size of training data, and it starts to saturate for our SVM model with 80%-90% of the experimental data for training. In contrast to that, the average AUROC remain comparable with varying training size, but the performance variances decrease with increasing training data size. Therefore, instead of doing 10-fold cross validation, a 5-fold cross validation might be sufficient with this size of data, as a 5-fold cross validation uses 80% of the data for training and the remaining 20% of the data for testing. Even a 2-fold cross validation could work as the AUPR is close to saturation with 50% of the data for training.

Deleted: [... [75]] -- Ref2.5 - Feature selection --<ASSIGN> ANS <PLAN> <STATUS>50% need more justification about the selection of six Reviewer Formatted Table predictors for the development of the integrated model. I Comment. agree that the selected epigenetic marker datasets are widelv available for many cell-lines from publicly available resources. Without doubt, this way increase the utilization of the method in new cases. My question is why six and not another combination out of the 30? Continuing the previous comment about optimality of the heuristically identified solutions, is there any guarantee that the integration of the selected six predictors is optimized? For example, one can apply an exhaustive search algorithm and find the best combination. One also can argue that since the performance differentiation with Random Forests is small, the latter classifier is more effective since it integrates an "out-of-bag" teature selection technique. For example, this is the biggest advantage of RFECS method that pooled together multiple epigenetic markers and identifies the most informative. Authors have to elaborate more on the available dimensionality reduction techniques to select the best combination of predictors. To keep it as simple as possible, combining filtering techniques such as mRMR or Gini index with the linear SVM is quite powerful and provides interpretable results. Deleted: Thanks to the referee for the question. [76] Author Thanks to the referee for the question. The 30 histone marks we Response tested are from drosophila experiments, and most of them of them dog not have available data even in top tier tissues and cell lines for mouse and human. We have created SVM as well as random forest models with all 30 epigenetic marks and added the performance of these models to supplement. Using these models you can identify the 6 epigenetic marks that provide the most information for enhancer prediction. In our model, we chose these 6 histone marks because we wanted to test the applicability of the model trained with fly data for predicting active enhancers and promoters in mouse and human tissues. We didn't seek to pursue an optimal combination of all Deleted: The 30 histone marks we tested are from drosophila experiments, and most of them of them histone marks. While optimality of plarks could potentially be used does not have available data even in top tier tissues to identify other histone marks that provide complementary and cell lines for mouse and human information about activity of enhancers and promoters, it could potentially reduce the applicability of the model to mouse and

		Deleted: ### Leave out this section, to be finished
Reviewer Comment	Separation of active STARR-seq peaks to promoters and enhancer based on the distance from known TSSs is the adopted practice, however it is too "quick and dirty". The truth is that, it is very difficult to discriminate sharply enhancers from promoters based on the distance from TSSs since promoters have frequently function of enhancers and vice versa, and both of them share similar transcriptional architecture and have similar properties (ref. PMII: 26073855). From a technical point of view and based on the existing results, I would like to see the performance of the deployed method by varying the distance from TSS for selecting enhancers and promoters for testing. If the extreme case the binary classification problem is transformed to one-class classification problem that the method should handle. An alternative way is to repeat the analysis, using appropriate CAGE-defined prooter and enhancer datasets that coincide with STARR-seq paks. There are also data from studies such as "Systematic dissection of regulatory motifs in 2000 predicted human enhancers using a massively parallel reporter assay" or High-throughput functional testing of ENCODE segmentation problems that could be used as baseline for benchmarking the performance of the method in a more orthogonal way. Author Response	same TF-binding sites? This might reveal that STARR-seq peaks that overlap with specific TFs such as p300 or CBP provide a better training dataset. Related to the comparison with ChromHMM and Segway. Both ChromHMM and Segway are based on probabilistic graphical models (HMM and Bayes). They should include a method of different type for example using SVM or Random Forest that is more close to what they have been developed. We compared with ChromHMM and SegWay as their enhancer annotation has been used in many publications as a way to define enhancer regions. Based on the referee's suggestion, we also did more comparison with other published methods, and we have included the results in our manuscript as shown below.	Deleted: specfic Comment [5]: +chengfei.yan@yale.edu help! _Assigned to chengfei.yan_
Excerpt From Revised Manuscript	In addition to the comparison with unsupervised segmentation based methods, we also compared with other published enhancer prediction tools, including CSIANN, a neural network based approach; DELTA, an ensemble model integrating different histone modifications; RFECS, a random forest model based on histone modifications, and REPTILE, a more recent published method that integrates histone modifications and whole genome bisulfite sequencing data. We used their published results and compared their methods with our model on the same experimental data reported in their paper(\cite()). The comparison was done in a tissue specific manner for all four mouse tissues with all required ChIP-seq and DNase experiment data available. For 3 out of 4 tissues in the comparison, our prediction shows higher AUROC than the other four published methods. In midbrain, the AUROC for our prediction is slightly lower than REPTILE and RFECS, possibly due to the data quality of the DNase experiment performed in midbrain. The DNase experiment of mouse E11.5 stage midbrain is marked as low spot score in ENCODE. We found that while 75% to 81% of the genome regions has DNase signals in the other three tissues, only 52% of the genome regions show DNase signal in the experiment in midbrain. It is also worth noticing that our model is trained using the drosophila STARR-seq data whereas the other methods were trained directly with mouse data. We believe that our method would have better performance if mouse STARR-seq data could be applied for training in our framework.	Formatted: Left Deleted: Deleted: Deleted: Ve show that our method also outperforms these previous approaches assessed by in vivo transgenic experiments

Indeed each each	didata haa a raadaut far all tigauga in tha amhruga	Figure 4D and 40

Indeed each candidate has a readout for all tissues in the embryos. Figure 4B and 4C use this experiment read out to evaluate the prediction. The ROC curve evaluates the false positive rate and true positive rate of our prediction in each tissue at different threshold, and the PR curve evaluates the precision and recall of the prediction. At random, the ROC curve is a diagonal line with AUROC of 0.5, and PR curve is a horizontal line with AUPR equal to the fraction of positives. In 4A the table contains the average ROC/PR of the evaluation results from six different tissues. We are reporting averaged numbers. We have modified the text to make this clearer.

We've rewritten the text to make clearer

ANC		

Acknowledging the fact that there are some circularity, this is in many methods and is due to current limitations. We have multiple validations

1. training data is different, with STARR-seq experimental validate 2. methods, not seeking for peaks, looking for pattern match

 Page 20: [69] Deleted
 Mengting Gu
 5/18/18 10:12:00 PM

To identify the enhancers active within a single cell-type in fly, Stark and co-authors showed that the STARR-seq peaks that overlap with enriched DHS or H3K27ac signal in the same cell-line were close to genes that had higher gene expression. In contrast, the STARR-seq peaks that overlapped with reduced DNase hypersensitivity overlapped with the repressive mark H3K27me3 and were situated close to genes with lower gene expression in the same cell-type. While STARR-seq identifies regions that could be potential enhancers or promoters, it does not guarantee that the region will be active or repressed in that cell-type. In machine learning models, the training data should be as well annotated as possible. As our attempt is to use the cleanest set of experimentally verified enhancers that could be active in a cell-type specific fashion, we used the experimentally active STARR-seq peaks that overlapped with DHS or H3K27ac peaks as our training data as these are more correlated with active regions in the genome as per the STARR-seq study.
